the rotating frame. Rotary saturation was first practised by applying an external longitudinal oscillating field parallel to the polarization direction of nuclear spins, in order to cause resonance saturation of a spin ensemble in the rotating frame. I was intrigued by the idea of flipping (nutating) a spin in a solid so that it would produce an internal 'local longitudinal dipolar field' which would cause rotary saturation of a neighboring spin characterized by an entirely different Larmor frequency. I first thought in terms of imitating the spin-lattice relaxation mechanism, by imagining that one replaces the Fourier component of lattice noise at the ^{35}Cl resonance frequency by a specific rotary saturation frequency component. This component would be produced by a neighboring Na spin, resonant with ^{35}Cl . But how could that be done? An intense rf field, impossible to produce, would be required to flip the Na spins in order to 'relax' the observed ^{35}Cl ensemble at its resonance frequency of 30 MHz!! Of course, one had to prepare the ^{35}Cl system in the rotating frame. The rotary saturation frequency would be much lower and the rf field could be generated. Sven Hartmann reminded me about Solomon's spin-locking technique.³³ That was the way to do it, and along with the rotating frame came the necessity of thinking in terms of spin temperature, expounded further by Lurie and Slichter.³⁴

It is interesting to point out that the method of 'dynamic nuclear polarization', introduced earlier³⁵ by Anatole Abragam and Carson Jeffries, can be treated as though it is a case of Hartmann-Hahn cross relaxation. In the rotating frame, electron spins acquire a low absolute spin temperature (with negative or positive polarization) and a Larmor frequency which closely matches the Larmor frequency of coupled nuclear spins at a higher spin temperature in the laboratory frame. This particular cross-relaxation process requires intense microwave electron spin excitation because a small fraction of the electron spin 'magnetic heat capacity' is utilized.

Directly following the work with Hartmann, a series of investigations involving variations of double resonance spectroscopy were carried out by Dick Slusher,³⁶ Russ Walstedt, and Dave McArthur,³⁷ and Gil Leppelmeier.³⁸ The dynamics of the double resonance process were studied in particular by Walstedt and McArthur, who very carefully and with great skill measured the fluctuation spectrum of the ^{19}F - ^{43}Ca spin-spin coupling operator in CaF_2 . This spectrum is characterized by a still-unexplained exponential function of the rotating frame ^{43}Ca Zeeman splitting over a wide range of cross-relaxation rates. Also the transient regime of spin population cross-coupling oscillations was measured and analyzed. The transient is a version of the oscillations observed earlier between coupled dipolar and Zeeman reservoirs brought suddenly into contact in the laboratory frame.³⁹

Self-Induced Transparency

Some time before Sven Hartmann obtained photon echoes,⁴⁰ I was curious about what effect zero-field NQR resonant absorption of ^{35}Cl might have on rf pulses matched to a transmission line filled with powdered NaClO_3 crystals. The experiment was attempted surreptitiously, because I suspected it would fail from the start. The transmission line had to be too long in order to see a significant effect. Jim Kemp, who came over from the Electrical Engineering Department to collaborate

on a pulsed EPR experiment, suggested that we try to look at the change in the properties of a propagating EPR pulse when it is tuned to the electron spin resonance of two ferrite spheres separated down the line from one another in a wave guide. The excitation of the first sphere by the pulse would cause the sphere to reradiate and drive to some extent the second sphere down the guide. Finally, the output pulse was expected to be some sort of superposition of driving and reradiated signals. We certainly saw signals, but they were too messy to interpret because of a combination of wave guide reflections and multiple spin wave modes excited in the spheres.

Again the propagation game was abandoned and resumed once more, this time after the photon echo⁴⁰ was revealed by Sven Hartmann at Columbia. Logically, in concentrating on the dynamics of newly found optical echoes, Hartmann made the approximation that laser pulses remained unaffected while propagating through a short length of ruby crystal. This was a setup suitable now for Sam McCall (a superb new thesis student) and me to look for propagation effects on a traveling wave laser pulse at resonance with ruby. By choosing a crystal long enough to include a sufficient number of absorption lengths, we confirmed experimentally what had been predicted in a small way by an ignored computer empirical analysis we published earlier as an abstract.⁴¹ Finally, thanks to Sam's computer and theoretical expertise, we were able to formulate a general description of self-induced transparency⁴² based upon analytical semiclassical solutions of the Bloch-Maxwell equations. Self-induced transparency was the first clear experimental example of soliton behavior in the form of optical traveling wave pulses.

The description of two-level systems in the Bloch-Maxwell model of the self-induced transparency experiment contains many ideas borrowed from the description of coherent transients in NMR. A number of pulsed laser experiments then followed over the years which demonstrated analogs⁴³ of pulsed coherent NMR transient phenomena. Of greatest utility were the results⁴⁴ concerning two-photon and Raman response of three-level systems, formulated in terms of the density matrix by Dick Brewer and myself. As a result of my collaboration with Dick Brewer at IBM over a number of years, his researchers inspired a number of laser thesis topics which I carried out with my students at Berkeley.

IN RETROSPECT

Several transient signal effects under conditions of driven rf excitation were reported in the early NMR literature. It seems to me that these transient effects provided sufficient information that could easily have led to the prediction and production of a FID signal. Perhaps the spin echo would not have been immediately predicted, but it would have been discovered eventually, if not by me, then by somebody else. In his first paper,¹ Bloch mentioned that free precession would result after the sudden reorientation of spins by a nonadiabatic dc field pulse. Jacobsohn and Wangsness reported⁴⁵ the measurements and theory of an NMR transient called the 'wiggles'. This is a beat phenomenon often seen in CW NMR when a small sweep magnetic field passes through the resonance condition, and the nuclear spins are tipped slightly to produce a transverse precessing magnetization. The Larmor frequency of this magnetization tracks with the externally

swept dc field, and beats with the fixed driving rf field after the resonance condition is traversed. In Torrey's paper⁷ on nutations, he mentions explicitly that no one had yet seen free nuclear induction signals. Inexplicably, neither he nor anyone else followed up that statement by applying a short rf pulse at resonance to see if a predicted FID could be detected. It was left for me to find it by accident! Volumes can be written about numerous cases of this sort in the annals of science.

Biographical Sketch

Erwin L. Hahn. b 1921. B.S., 1943, Juniata College; US Naval Reserve, 1944–46; Ph.D., research associate, University of Illinois, 1949–50. Instructor, postdoctoral worker, Stanford University, 1950–52; IBM Watson Laboratory, 1952–55; Professor of Physics, University of California, Berkeley, 1955–present. Research specialties: pulsed NMR and laser phenomenology, spin–spin coupling, double resonance, nuclear quadrupole resonance.

Hall, Laurance D.: NMR Studies of Carbohydrates

Laurance D. Hall

University of Cambridge, Cambridge, UK

My involvement in nuclear magnetic resonance spectroscopy was the result of a traumatic experience. One Friday in 1959 I had obtained the last elemental microanalysis to show that I had completed the synthesis of a series of furanose carbohydrates. By the following Monday I had convinced my supervisor, Les Hough, that all was well and on Tuesday afternoon I went to the library of the Chemistry Department of Bristol University to write my first paper. Browsing through the latest issue of the *Journal of the Chemical Society* to gain some sense of the appropriate style, I was appalled to find a paper by L. N. Owen of Imperial College which described my work! Fortunately I had made both the D- and L-series of derivatives, and was able to publish¹ the work in full; nevertheless I was so upset that I decided there and then that I would find my own Ph.D. topic, remote from the interests of others. Late that same evening, unable to work, I returned to the library and started to browse through the new monographs that were kept on a separate shelf by the entrance door. One of these, 'High Resolution NMR' by Pople, Schneider, and Bernstein,² attracted my attention for no particular reason. Yet within minutes I was riveted; one section showed the proton NMR spectra of fully acetylated pyranose sugars, the work of Lemieux, Kullnig, Bernstein, and Schneider.³ I did not understand how the spectra had been obtained nor the meaning of the terms 'chemical shift' or 'coupling constant', yet it was absolutely clear to me that here was the technique which would revolutionize structural analysis of carbohydrates; more importantly, I had a wonderful collection of furanose sugars and it appeared that nobody had yet studied such substances; it also occurred to me that since the H-1:H-2 coupling constants of pyranose sugars varied with the relative stereochemistry of the C-1:H-1 and C-2:H-2 bonds, I might be able to work out the shapes of my furanose sugars and thereby understand the stereospecific dependencies of their reactions; furthermore, since I had systematically varied the substituents attached to O-3 of my glycofuranose sugars I would be able to demonstrate the specific chemical shift changes induced by functional groups, something at that time unknown, but potentially important.

By now it was early morning, too late to go home, so I stayed in the library until Les Hough came into the lab, and I told him that I had decided to abandon my synthesis work and take up NMR spectroscopy instead! In retrospect, and having since supervised a huge number of my own Ph.D. research students, Les could have attempted to dissuade me; indeed, he did point out that Bristol University had no NMR spectrometer, that he knew nothing about the method, and that the prudent thing to do was to get my Ph.D. first and then learn about NMR as a postdoctoral fellow elsewhere. Of course, I would have none of this, and went off to read all I could about NMR; this involved me in the *Journal of Chemical Physics* and the *Canadian Journal of Chemistry*, which were far removed from organic synthesis. I also talked to all and everyone about my ideas; again in retrospect my behavior must have verged on the

noxious, but I was blissfully unaware of this at that time. Then came the second of a series of lucky breaks; I was a teaching assistant to an undergraduate inorganic chemistry laboratory supervised by E. W. Abel and discovered that he had been a postdoctoral fellow at Imperial College, London and that he actually knew something about NMR (at that time he was the only one in Bristol who did!). I must have made life hell for him since I bombarded him with questions: one day he made an offer; on Friday he was to go to Imperial College; he would take three samples and try to persuade someone to run their spectra; the deal was that until I had interpreted them I would not talk to him or anyone else about my ideas for NMR! Little did I know that that promise was to mean that I was to be in purdah for nine months. In any event, the following week he returned with three envelopes each containing narrow strips of thermal sensitive paper with black squiggles on them and some strange hieroglyphics such as 'SSB' or 'ASB,100'. None of that mattered since I could see that one of the spectra contained nearly as many separate peaks as there were different protons in the molecule . . . something that was quite different from the spectra published by Lemieux and co-workers. I eventually persuaded the departmental photographer to make some photographic enlargements of those spectra so I could calibrate them, learned that 'ASB' was 'Audiomodulation Sideband' and 'SSB' was 'Spinning Sideband' and was in business.

Nine months later I was able to hold an intelligent discussion with Eddie Abel, but was still unable to understand my spectra fully because there were too many 'doublets' and not enough 'quartets'. Then came my second break, with the publication⁴ by M. Karplus of his ' $\cos^2 \theta$ ' interpretation of the stereospecific dependence of coupling constants. Now I could see that my furanose sugars must be in a conformation in which one of the pairs of C-H bonds had a dihedral angle of 90° and hence a zero coupling constant, something that had never been seen before. My problem was that I still could not assign the individual resonances; I needed more spectra! Then came my third break, because I remembered that when I had worked one summer for ICI Dyestuffs Division at Manchester I had been shown an NMR spectrometer, something I had completely forgotten up to that point. I wrote immediately to Mrs. Neil, their academic liaison officer, telling her my story, and to my delight received from her the offer of spectra for any 12 samples of my choice. Those were sent off the next day, and several weeks later I received the results with a covering letter from Jack Becconsall who had run them, to the effect that some of them looked interesting. Elatedly I rushed off to tell my then flatmate and friend Les Rigby . . . and hence to the next stroke of luck. He was being visited by Keith McLauchlan who had been a student at Bristol, and who I discovered was now a postdoctoral fellow at the National Physics Laboratory at Teddington working with John Pople; he not only had access to an NMR spectrometer, but was working with Ray Abraham on the shape of another set of five-membered rings, those of hydroxyproline derivatives. The following week Keith returned to say that he and Ray were willing to run my samples; my reply was 'I want to go with the samples'. In due course it was agreed that he would take those of my samples he had chosen and that a month later I could go to Teddington for a one-day visit, no longer. When I arrived there was some gloom since all the samples they had run had given overlapping resonances.

That did not surprise me because I had already decided that the samples Keith had chosen were not the best suited to the project . . . I had those in my pocket! It turned out that one of the other scientists was going on holiday that next week and Ray Abraham suggested that, although the project was likely to fail, perhaps I might like to run some samples myself. After an introduction as to how to crank a magnet pole face to improve the field homogeneity and how one could track the sweet spot by moving the probe within the magnet to improve the resolution (this was before we had either shim coils or baseline stabilization) I was ready for my first spectrum (3-*O*-acetyl-1,2-*O*-isopropylidene- α -D-glucofuranose); everyone gathered round and kept still whilst the chart recorded a spectrum with seven completely resolved proton resonances, each with close to baseline resolution. By then I knew enough about chemical shifts to say with reasonable confidence which was which.

After that there was no question about abandoning the work, nor even of my returning to Bristol; simply I was going to push this as hard as I could. Of course, there were some logistical problems to overcome, such as my undergraduate lab demonstration duties in Bristol, Les Hough my supervisor, and how I could pay to live in London. In the event, I stayed with my parents and spent three hours each day commuting diagonally across London and started writing papers.⁵ I also listened carefully to the other members of Pople's group which at that time included Tom Connor and Ray Freeman. Tom was from Chris Reid's laboratory at the University of British Columbia and he taught me how to make dry, ethanol-free chloroform (stand it over silica gel) and how to measure H–O–C–H couplings and then 'decouple them' by adding a trace of trifluoroacetic acid; I put that to good use for my sugars. Ray Freeman and I soon found that we shared a common lack of interest in cricket, something which put us both somewhat apart from the rest of Pople's group. So, whilst the others played cricket in the sun, he and I sat in the shade and I talked to him about my hopes whilst he listened patiently. One Wednesday morning he told me that he had just built a new machine and that he would use it to assign all my proton resonances, and if I would make up a solution he would run the experiment that morning. After coffee we went to the lab and Ray went through his routine of rewiring the Varian DP-60 spectrometer to what was then the world's first 'frequency sweep' spectrometer; this involved taking from a clothes hanger behind the lab door, a bundle of cables with banana plugs on each end, and using them to connect two small metal boxes to the DP-60. The dials were unlabeled and nobody but Ray had any idea of how the apparatus worked. However, on that day everyone trooped into the lab for the first demonstration of Ray's latest toy. He put me on the spot by asking me which pairs of resonances were coupled (remember that there was a zero coupling); within a few minutes he had proved that my previous assignments based on chemical shifts were correct, and by lunchtime we had completed the full cycle of decoupling experiments. After lunch, while all the others went off to cricket, Ray and I wrote a paper which was sent off to the Chemical Society the following afternoon.

By now it was clear that my thesis was to include a great deal of NMR spectroscopy and that I was unlikely to spend much time at Bristol, so Les Hough was invited to come for a visit and a deal was struck whereby I would visit Bristol a week every month to fulfill my lab demonstrating activities (having swapped with my friends so that my duties were

bunched together). In due course (January 1962) I returned to Bristol to write up my Ph.D. thesis, which was subsequently examined by Peter Schwarz from Edinburgh; after 10 minutes, during which he made several excellent suggestions about my chemistry, he closed the examination and asked me to spend the next two hours explaining to him how NMR worked. I was then 'invited back' to Bristol to give a lecture on my work; this was unprecedented, but I can still remember how that, my first formal lecture, felt . . . I feel the same before any major lecture. By then I had had offers of postdoctoral fellowships from Frank Anet at Ottawa University and from Lloyd Jackman who was moving from Imperial College to Melbourne. I decided to go to Ottawa since that was also where Bernstein and Schneider were. There were other distractions too; such as being offered a job by Frank Rose to set up an NMR machine for ICI Pharmaceuticals at Alderley Edge (a job which Geoff Bedford did far better than I could ever have done); such as going to my first international symposium (on carbohydrates at Birmingham), where I first learned that some abstracts claim more that the lecture presents; and getting married.

My move to Ottawa in August 1962 brought about a mixed set of developments. The bad news was that Frank Anet had decided to go on sabbatical within a few weeks of my arrival; so once again I was left without a supervisor, but this time in charge of a lab full of graduate students, one of whom was 15 years older than myself. The good news was that I had access to a 60 MHz spectrometer and was an honorary member of the NRC lab where Bill Schneider and Harold Bernstein worked. Furthermore, both Margaret and I enjoyed Canada; our first daughter, Gwendolen, was born in May 1963, and I decided to try to make a career in Canada instead of returning to England. So in March 1963 I went to Pittsburgh to my first ENC meeting, at which I made friendships which have lasted my lifetime. On my return I found invitations to visit Queen's University and also the University of British Columbia. I arrived in Vancouver on a beautiful sunny day, fell in love with the scenery, gave a stimulating lecture and was eventually offered a post of 'Instructor II', which I later found was even lower than Assistant Professor. A memorable drive across Canada in August 1963 then started 25 years at UBC which was only terminated by the machinations of Joachim Burhenne, then Head of Radiology, who wished to control magnetic resonance imaging in Vancouver. During those years at UBC I learned how to run a research group, build NMR machines, and also that my love of my science was probably stronger than was compatible with a balanced life; however I run ahead of myself.

Based on my own experience and that of Lemieux, it was clear to me that carbohydrates provided an ideal skeleton for studying the stereospecific dependencies of NMR parameters; thus the pyranose ring was generally conformationally rigid, and by using appropriate substitution it was feasible to obtain essentially first-order spectra, even at 60 MHz. My first research involved the synthesis of a wide variety of specifically fluorinated carbohydrates; those enabled us to delineate the stereospecific dependencies of ^{19}F – ^1H and ^{19}F – ^{19}F coupling constants,⁶ and the intrinsic chemical shift differences between the axial and equatorial orientations. Subsequent studies involved phosphorus-31,⁷ mercury-199,⁸ and thallium-203.⁹

My interest in conformational analysis of carbohydrates also prompted me to explore the possible use of lanthanide

shift reagents, but this was not a convenient procedure. However, our studies¹⁰ of the spin–lattice relaxation rates of the protons of sugars was a far more rewarding area. It was possible to prove rigorously that their relaxation was entirely via the intramolecular dipole–dipole mechanism.¹¹ Furthermore, methods were developed whereby specific interproton relaxation contributions could be measured quantitatively; these involved use of specific deuteration,¹² or of selective proton T_1 measurements.¹¹ Undoubtedly the most important discovery was the interproton relaxation between the H-1 proton on one ring and those on the adjacent ring;¹³ in the form of specific interring nuclear Overhauser enhancement measurements this is now widely used in oligosaccharide conformational analysis.

During the early 1970s it became clear that the increased spectral dispersion produced by superconducting solenoid magnets would revolutionize the ease with which proton spectra could be assigned. Sadly, the Canadian NRC had decided that they would not provide such devices for any Canadian university, so I decided to assemble my own. Thus a 60 MHz Bruker console was purchased from the fledgling company Nicolet and upgraded to 270 MHz operation by the electronics shop in the UBC Chemistry Department. A 270 MHz magnet was purchased from Oxford Instruments, a crude proton-only probe constructed (no mean feat at a time when probes were regarded as being black magic), and we had access to high-quality spectra. It was fortunate both that Dave Dalrymple, then at Nicolet, had written software for processing the then new class of two-dimensional NMR spectra, and that I had an outstandingly able graduate student, Subramanian Sukumar. That combination soon enabled us to describe for the first time how the proton 2D J resolved spectroscopic technique could be used to unravel complex carbohydrate spectra,¹⁴ that was followed by the use of NOESY and COSY spectroscopy. We were then joined by Gareth Morris from Ray Freeman's group, who built our first ^{13}C – ^1H probe and demonstrated the power of 2D heteronuclear correlation spectroscopy¹⁵ as a tool for the carbohydrate chemist. I remember the elation I felt when I realized that that method gave us the effective resolving power of a 10 000 MHz proton spectrometer; the chemical shift sensitivity of ^{13}C is 40-times that of the equivalent proton resonances. Our work in 2D NMR was hugely aided by the fact that we had a second Nicolet computer set up as a data-processing station; that was regarded as being a luxury at that time!

Exciting as it was, the development of that 270 MHz spectrometer was to be the nemesis for my carbohydrate spectroscopy, since by 1980 the performance of our homebuilt instrument was no longer competitive with the new spectrometers available commercially. Rather than abandon the instrument, Sukumar and I decided to convert it to an 'NMR microscope'. We found that this was straightforward, and that the Nicolet 2D software could be used to plot out in contour format the results from imaging of simple objects.¹⁶ Those exciting developments enabled us to be the first in Canada to study NMR imaging. Inexorably, I found myself drawn from the 'Laboratory' to the 'Hospital' where by 1983 I had installed the first MRI scanner in Canada. Inexorably too, I was dragged into the jungle of local medical politics; the imaging went well, the politics equally badly and job offers abounded; in 1984 I accepted the invitation to be the first holder of the Herchel Smith Chair of Medicinal Chemistry at Cambridge University. This is a clinical chair and has enabled me to fulfill at least

some of the hopes which prompted my move into MR imaging. Having built the Institute I am now returning to my interests in carbohydrates, this time to polysaccharides; two examples will suffice to explain what can be achieved. Since the NMR properties of water are influenced by dissolved polysaccharides, it is possible to develop MRI protocols to map in space and time the location of polysaccharides; for example, we have shown¹⁷ that when calcium alginate is formed from sodium alginate and calcium chloride, the resultant gel is not homogeneous, rather there is a higher concentration of alginate at the outside of the gel structure. More importantly, we have demonstrated¹⁸ that MRI can be used to study cartilage structure and composition in the articular joints of man. Changes in cartilage due to osteoarthritis are of great importance to the pharmaceutical industry, and we now have the most promising method for detecting the early onset of that disease and for monitoring not only the natural progression but, possibly, the efficacy of new drug treatments.

It has been an interesting experience to write this article, since the feelings of 1959 are as vivid now as they ever were. I now have about 12 years to go before I am forced from my research chair and I fully intend to use them to explore the wonderful synergy between 'carbohydrates' and 'NMR'. The fortunate experiences of 1959 have dominated both my scientific career and my private life, and I have no regrets about continuing to explore the creative opportunities which connect those two scientific disciplines.

Biographical Sketch

Laurance D. Hall. b 1938. B.Sc., 1959, Ph.D., 1962, Chemistry, University of Bristol, UK. Postdoctoral fellow, Ottawa University (with Frank Anet). Successively Instructor II, assistant, associate, and full Professor, University of British Columbia, Canada. Currently first holder of the Herchel Smith Chair of Medicinal Chemistry, University of Cambridge, UK. Approx. 400 publications. Research specialties: all aspects of magnetic resonance imaging.

Harris, Robin K.: Chemical Magnetic Resonance goes Multinuclear

Robin K. Harris

University of Durham, Durham, UK

INTRODUCTION

In the early days of NMR, when it was exclusively the realm of physicists, a variety of nuclei were studied. Thus, the chemical shift phenomenon, which was to prove such a boon to chemists, was first discovered^{1–3} for ^{14}N , ^{19}F , and ^{59}Co . However, it soon became evident that the highest resolution was only achieved for spin- $\frac{1}{2}$ nuclei.

THE PROTON, FLUORINE-19, AND PHOSPHORUS-31

I first came into contact with NMR during my undergraduate days at Cambridge. At that time (1956–59) chemical NMR in the UK was in its infancy, and the teaching of it had only just been included in the Cambridge curriculum. It seemed an exciting area and I decided to study for a Ph.D. in NMR under Norman Sheppard, who was responsible for the newly-acquired Varian 40 MHz spectrometer. I was introduced to the delights of field cycling and yoke-bending of the magnet to achieve good B_0 homogeneity. The spectrometer was only really suitable for examining nuclei with high natural abundance, and so chemical applications of ^1H and ^{19}F field sweep NMR became the subject of my thesis.

One consequence was that homonuclear indirect spin–spin coupling was of importance, and it frequently led to the occurrence of second-order spectra. Spectral analysis was a growth industry at the time. Much was, of course, already understood, and the seminal monograph by Pople, Schneider, and Bernstein⁴ had just been published. However, many wrinkles remained to be discovered. Others in Norman Sheppard's group were, for example, engaged⁵ in analyzing ' ^{13}C satellites'. It was interesting for me to be involved in the early use of computers to examine ABC and ABCX spectra. Having just read the paper by Whitman et al.⁶ on the 'composite particle' method of viewing groups of magnetically-equivalent nuclei, I happened to notice some interesting ^{19}F spectra being obtained by a research student, Ken Packer, in the Inorganic Chemistry Department, and I recognized these to be classic examples of the AB_4 type I had been thinking about.⁷ Analysis was attractive since a computer was unnecessary, only 2×2 submatrices being involved. The full spectra could be readily broken down into independent parts, and the concept of 'subspectral analysis', subsuming some earlier concepts and examples, was seen to have general validity, especially by Peter Diehl in Basel, with whom I collaborated to produce a review article.⁸

Figure 1 Observed (a) and calculated (b) 60 MHz ^1H spectra of tetramethyldiphosphine disulfide in solution in CDCl_3 . [Spectrum redrawn from Ref. 9.] The zero on the scale is the chemical shift ($\delta_{\text{H}} = 1.96 \text{ ppm}$)

On finishing my Ph.D. I went to the Mellon Institute, Pittsburgh, where, after a year in vibrational spectroscopy, I joined Aksel Bothner-By's group, the home of the famous LAOCOON spectral analysis computer program (produced by Aksel with Salvatore Castellano). Here I again benefited by seeing someone else obtaining interesting spectra (on the marvelous Varian A60)—in this case R. G. Hayter who was looking at $(\text{CH}_3)_2\text{P}(\text{:S})\text{P}(\text{:S})(\text{CH}_3)_2$. This has a symmetrical spin system of the type $[\text{X}_3\text{A}]_2$, and the spectra (Figure 1) could be interpreted⁹ very simply once one understood the theoretical basis. This type of case turned out to be very common in coordination chemistry and had the nice twist that $|J(\text{P,P})|$ was obtainable by simple inspection of the proton spectrum (Figure 1). Back in the UK in 1964, at the new University of East Anglia, I was able to exploit the spectral analysis concepts, helped by students such as Elliot Finer and Tony Cunliffe, and to apply them to a wide range of problems in phosphorus–fluorine chemistry (especially in collaboration with German inorganic chemists Reinhard Schmutzler and Gerhard Hägele) and other areas. Such studies are now, however, frequently bypassed by sophisticated experimental procedures.

CARBON-13 AND SILICON-29

In the mid-1960s attention was turned by a few pioneers, such as Jake Stothers and Dave Grant, to the possibility of observing the 'dilute' nucleus ^{13}C (still with continuous wave

Figure 2 Expansion of part of the 99.36 MHz ^{29}Si spectrum of an aqueous potassium silicate solution, with enrichment of ^{29}Si to 95.3%. At least 20 species are in dynamic equilibrium in the solution, and the partial spectrum illustrated can be assigned to the novel cage structure I (in which Q^2 and Q^3 indicate silicate environments involving two and three siloxane bridges, respectively). The arrows indicate peaks arising from molecules containing ^{28}Si sites. [Spectrum redrawn from Ref. 12]

methods of course), and I was pleased to spend my first sabbatical leave (five months in 1968–69) at the University of Utah with Dave Grant to learn about this area. Just about that time, use of the Fourier transform principle, pioneered by Richard Ernst,¹⁰ ‘transformed’ the NMR of insensitive nuclei, and back home the University of East Anglia was soon able to acquire a commercial FT spectrometer. The rush, worldwide, into ^{13}C NMR was considerable (ironically for me, no second-order spectral analysis was generally needed for proton-decoupled spectra). Although I joined in, this concentration on ^{13}C seemed to me to ignore other possibilities, and I was attracted to using the ^{29}Si nucleus, as a handful of other groups were doing. Barry Kimber was the first person in my group to study ^{29}Si NMR and he showed that the technique is invaluable for examining polymeric silicones,¹¹ since excellent dispersion of signals can be obtained. The quotation at the beginning of Barry’s Ph.D. thesis is one of the most piquant I have come across:

... 19 Down: It sounds foolish to study this element (7). The Times Crossword Puzzle No. 13 231.

However, the quotation was arguably more appropriate for alkaline silicate solutions, the absence of coupling being a considerable hindrance to assigning the plethora of signals. The answer lay in the use of ^{29}Si isotopic enrichment with which we obtained the first spectra. At one point, I believe we purchased the total supply (at least in the UK) of ^{29}Si -enriched silica—which is one way to stymie any competition! Soon we progressed to the first very-high-field ^{29}Si spectrum (Bruker WM500, courtesy of Bill Hull in their applications laboratory in Karlsruhe) of such samples. With the ^{29}Si enrichment, coupling became important, and in his Ph.D. with me Chris Knight used both first-order and second-order spectra to yield the first unequivocal structural determination of many species present in the solutions (Figure 2).

OXYGEN-17 AND SULFUR-33

With few exceptions, the large linewidths often found for quadrupolar nuclei (because of the short transverse relaxation times) made them substantially less popular than the spin- $\frac{1}{2}$ cases. This was particularly so for ^{17}O and ^{33}S , which are the only magnetically-active nuclei of these chemically-important elements, since they also suffer from low natural abundance (0.037% and 0.76%, respectively). Sensitivity is therefore a big problem, and there are additional difficulties associated with the relatively long dead-times for the electronics of high-resolution solution state spectrometers. Oxygen-17 studies were of interest to Norman Sheppard and Ioannis Gerothanassis at the University of East Anglia in the mid-1970s. They were aided by the availability of isotopically-enriched H_2^{17}O . Sulfur enrichment is far less common, and I became interested (with Peter Belton of the nearby Food Research Institute) in the extent to which ^{33}S could be used at natural abundance in chemical applications. Together with a Ph.D. student, Jane Cox, we made some contributions¹³ to the general debate in this area, though it became clear that such ^{33}S NMR is only attractive for a few specific chemical types.

AND THE REST

During the first half of the 1970s, many groups were exploring the chemical applications of a variety of nuclei. The problems of low magnetic moments (and hence both low resonance frequency and low sensitivity), low natural abundance, and high quadrupole moments inhibited developments for some nuclei for a while, but it became clear that nearly all the elements were accessible. Since it seemed the ideal time to survey the whole area, I collaborated with Brian Mann to plan and edit the book ‘NMR and the Periodic Table’.¹⁴ At that time only seven elements with suitable nuclei (Ni, Zr, Ru, Pd, Hf, Ir, and Au), apart from the lanthanides and radioactive cases, had *not* been the subject of chemical NMR studies, and most of these found use shortly afterwards.

AND SO TO SOLIDS: REVISITING ^{13}C , ^{29}Si , ETC.

Up to 1976 I had only been dealing with solutions. However, the work of John Waugh’s group on cross polarization¹⁵ opened up new vistas, and I had some interesting discussions with Ken Packer on this area which resulted in us making a joint application to the UK Research Council for a grant. Ken had, coincidentally, been appointed to the permanent academic staff at the University of East Anglia the same year that I had, and he had developed research in broadband and relaxation NMR. The combination of his experience and of my own in pulsed FT NMR seemed ideal for CP work on solids, and we collaborated in this area until we both left East Anglia in 1984. In the middle of preparing our application, the first article¹⁶ on the CP MAS combination appeared and led us to alter our application considerably. It was successful, and our group (especially Barry Say and Giovanni Balimann) soon constructed the first suitable spectrometer in the UK. We concentrated on ^{13}C at first (especially on polymers and pharmaceutical polymorphs), with Alan Kenwright exploring

both areas in his Ph.D. work—and thereby missed a trick in not repeating the quick transition to ^{29}Si of my solution state FT studies (though we did give some advice to John Thomas and Jacek Klinowski in their pioneering work on zeolites in collaboration with Colin Fyfe).

However, there were plenty of other aspects to work on, and we produced, *inter alia*, some of the early results¹⁷ on the splittings in spin- $\frac{1}{2}$ MAS spectra arising from residual dipolar interactions with quadrupolar nuclei, which has remained one of my interests.¹⁸ More recently, my group (especially Matthew Leach and David Apperley) has become involved in using MAS for looking at ceramic materials. Cross polarization is inapplicable in most cases because of the absence of protons, and long ^{13}C and ^{29}Si relaxation times ($T_1 \sim 1\text{ h!}$) can cause problems, but the spectra yield much useful information. Moreover, isotopic enrichment again yields dividends, especially for ^{17}O and ^{15}N NMR,¹⁹ which can give information on crystallographic order in situations where X-ray diffraction studies encounter problems.

HEAVY-METAL SPIN- $\frac{1}{2}$ NUCLEI

Although slow to see the potential of ^{29}Si NMR for solids, we did start to look further down the Periodic Table and became particularly interested²⁰ in ^{119}Sn , ^{207}Pb , ^{199}Hg , ^{195}Pt , and ^{113}Cd , with Pat Reams's Ph.D. work providing some early examples. These nuclei are very suitable for solid state NMR and very informative chemically, especially because of the frequently large shielding anisotropies encountered. Ken Packer and I were persuaded by Bob Griffin (in a restaurant in London during a Royal Society meeting in 1980) that spinning sidebands are more of a blessing than a bane, and my group has utilized them (as have others) for new types of spectral analysis—for instance looking at the interplay between dipolar coupling, indirect coupling and shielding tensors²¹ (Figure 3). Solid state tin-119 NMR has been a special interest in my group since I moved to the University of Durham in 1984, reinforced by Angelika Sebald spending a couple of years in the group. Prior to our experiments, there was only one mention of its use,²² but there are some fascinating facets, and it is now a technique of choice for insoluble tin compounds.

It seems to be time for a monograph on 'NMR of solids and the Periodic Table', especially since techniques^{23,24} such as DOR, DAS, and SINMR make observation of resonances from quadrupolar nuclei more informative.

AND BACK TO SQUARE ONE: ^1H , ^{19}F , AND ^{31}P (IN SOLIDS)

The techniques for high-resolution spectra of abundant spins in solids, i.e. combined rotation and multiple pulse spectroscopy (CRAMPS), which were introduced by Gerstein and co-workers²⁵ and independently by East Germans,²⁶ have proved to be more difficult to implement than CP MAS methods for dilute spins. However, much is to be gained from their application, especially for studies of hydrogen bonding and of fluoro polymers, both of which are of interest to us in Durham,^{27,28} as demonstrated particularly by Geoff Nesbitt, Larry Merwin, and Pete Jackson in their Ph.D. work. Of

Figure 3 Tin-119 cross-polarization magic angle spinning spectrum of triisobutyl fluoride at 74.63 MHz, with high-power proton decoupling. The three centerband peaks indicated by arrows show the tin is five-coordinate in the solid state (coupled to two fluorine nuclei). Spinning sideband analysis exploiting the interplay between dipolar, shielding, and indirect coupling tensors gives detailed information. [Spectrum taken from Ref. 19b.]

course, as we have shown²⁹ for ^{31}P , multiple pulse methods can be combined with CP MAS to give better resolution at modest spinning speeds, though usually acceptable spectra can be obtained without such complications. We have also proved that $^1\text{H} \rightarrow ^{19}\text{F}$ CP MAS with high-power proton decoupling is feasible.³⁰

POSTSCRIPT

For chemical applications, NMR is undoubtedly now the most generally useful technique available, partly because it can be applied to all phases of matter, but also because it is element-specific, and thirdly because nearly all elements in the Periodic Table contain useful nuclei. It has been a rewarding experience for me to watch these matters develop to full fruition over the past 35 years. As with all academics, the research in which I have been involved has only been possible because of the participation of research students, postdoctoral fellows, visiting scientists, and collaborators at other institutions. Space restrictions prevents mention of most of their names here.

Hennel, Jacek W.: Poland. Early NMR

Jacek W. Hennel

Niewodniczanski Institute of Nuclear Physics, Krakow, Poland

The start of NMR research in Poland was strongly affected by the conditions which arose in the country as a result of World War II. A few years had elapsed since the discovery of NMR before the experiment could be repeated in Poland. The reason was the state of destruction in which the Polish scientific community found itself at the end of the war. A great number of scientists had lost their lives, most of them murdered in accordance with Nazi and Soviet policy to exterminate Polish intelligentsia. Polish universities had remained closed from the autumn of 1939 until January 1945. Laboratories were destroyed, and even teaching at the grammar school level was strictly forbidden by the German invaders. During the war only a fraction of young people (like the author of this note) were able to benefit from the secret school system organized under the auspices of the Polish Government in Exile in London. Academic staff, especially professors, not only lost their jobs but even had to disguise themselves as uneducated people in order to survive.

At the end of the war, the organization of teaching and the rebuilding of laboratories were the most urgent tasks of Polish physicists. In spite of formidable obstacles such as the postwar economy of the country, lack of educated people, and Communist restrictions, academic life was rapidly recovering from the destruction. The old universities which found themselves in the new Polish state were immediately opened, a number of new ones were founded, young people were hired, scientific journals subscribed to, and libraries modernized. There was also some help from abroad. A great number of young people were admitted to the universities in 1945 and the following years to study physics.

In 1948 the Soviet authorities imposed a system of strict Communism and Stalinist terror on Poland. For science this meant an end to freedom of speech and isolation from abroad, both east and west. These heavy restrictions lasted a few years. The symbol of their removal was the International Conference 'Atoms for Peace' held in Geneva in 1955 in which a few Polish scientists were allowed to take part.

At the Jagiellonian University at Krakow (the oldest Polish university, founded in 1364) a special chair for nuclear physics was established in 1946 and given to Henryk Niewodniczanski, who had been Professor of Atomic Optics at the King Batory University in Vilna before the war. That old Polish university could not be restored after the war and hence Prof. Niewodniczanski moved to Krakow together with a small number of collaborators. As a relatively new branch of nuclear physics not demanding expensive equipment, NMR was just the right subject of research for the new laboratory. The initiative was taken by one of Niewodniczanski's former Vilna students, Andrzej Z. Hryniewicz. He and two other newly graduated members of the staff, Jacek W. Hennel (the present author) and Olgierd K.-Daszkiewicz, started construction of an NMR apparatus about 1951 and obtained, in 1953, the first NMR signal observed in Poland.

There were no people acquainted with NMR in Poland and, since personal contacts abroad were forbidden, we had to depend solely on the literature. The paper by Bloembergen, Purcell, and Pound (BPP)¹ turned out to be our major source. The apparatus consisted of an electromagnet of 15-cm pole face diameter fed from a large stationary battery set, a simple amateur radio signal generator (a Czechoslovakian product), a Soutif-Gabillard high-frequency bridge, a German radio receiver tuned to 28 MHz and a German oscilloscope. Equipment left by the defeated German army (Wehrmacht) was at that time the main source of electronic supplies available to the Polish physical laboratories. The magnet, the bridge, and the Helmholtz coils for modulation were made by ourselves. The sample was water in a vial.

Although it was very primitive, our apparatus had at that time quite a good scientific capability. It was immediately used for the investigation of NMR in water flowing through a tube. The first idea was to study the influence of spin-lattice relaxation on the signal,² the second was to demonstrate nonadiabatic passage in liquids³ since this phenomenon was known only in solids, and the third was to mark the exact volume of the flowing water by such a passage and differentiate between laminar and turbulent flow on the basis of the shape of the signal.⁴ After considerable reconstruction by G. Zapalski, the apparatus was also used for measurements of spin-lattice relaxation times T_1 in different liquids. An original method of T_1 measurement was developed.⁵ It was based on fast adiabatic transitions. The signal was recorded on photographic paper with the use of a mirror oscillograph. The problem studied was the temperature dependence of the function $T_1 h/T$ (where h is the viscosity and T the absolute temperature). According to the theory of BPP this function should be constant. We found that it decreases with temperature.⁶ The first achievements were reported at the Colloque AMPERE in Paris in 1958. This was possible because the restrictions on foreign travel had been relaxed by then.

Hryniewicz withdrew from NMR research in 1960 because of his involvement in gamma spectroscopy. Leadership of his group was taken over by Hennel. Daszkiewicz specialized in the construction of spin echo apparatus. His first model was finished in 1955 and the second one with a digital programmer in about 1960. This second model was suited for CPMG experiments and served for relaxation research in protein solutions.⁷ During the next few years a number of new young people joined the group, among them K. Krynicki who later emigrated to England and collaborated there with Professor J. G. Powles in the study of NMR in liquids, J. Blicharski, who discovered the interference effect of interactions in relaxation,⁸ and a few years later by A. Jasinski, who more recently initiated NMR imaging research in Poland.

A few years after the first NMR signal was obtained in Krakow, other physical laboratories in Poland started to work on NMR. In January 1957 an NMR signal was observed by K. Antonowicz at the Copernicus University in Torun. His scientific interest was NMR in flowing liquids, mainly relaxation.⁹ A strong NMR group was created at the Mickiewicz University in Poznan by Professor A. Piekara. His young students, J. Stankowski and J. Angerer, built NMR apparatus for the investigation of flowing liquids in 1959 and at the same time another of his students, Z. Pajak, was sent to Paris for a year to work on high-resolution NMR¹⁰

under the supervision of Professor Rene Freyman. Pajak and Stankowski formed two separate NMR groups in Poznan, one at the university and one at the Institute of Molecular Physics.

In about 1960 commercial spectrometers became available, enabling chemists to apply NMR to their problems. Nowadays there are three NMR superconducting magnets working in physical laboratories and six in chemical ones.

Development of NMR research in Poland would not have been possible without international contacts. In this respect an important role was played by the European learned society known as the Groupement AMPERE and by Professor E. R. Andrew, the famous British pioneer of NMR who over the past 35 years has invited many Polish physicists to collaborate with him in Bangor, Nottingham, and Gainesville.

Jacek W. Hennel. b 1925. M.Sc., 1950, Ph.D., 1960, Jagellonian University of Krakow. Research fellow, University College of North Wales, Bangor 1959–60 where he worked under the supervision of Professor E. R. Andrew. Successively assistant and professor, Niewodniczanski Institute of Nuclear Physics, Krakow, Poland. Currently Head of the Department of Nuclear Radiospectroscopy, Niewodniczanski Institute of Nuclear Physics. Research field: solid state NMR. Books: 'Introduction to the Theory of NMR' (in Polish) (1966) and 'Fundamentals of NMR' (1993) with J. Klinowski as co-author.

Hinshaw, Waldo: Notes on the History of MR Imaging from my Perspective

Waldo Hinshaw

Imatron, Inc., South San Francisco, CA, USA

The following notes describe the advent of clinical MR imaging from the point of view of someone who had the uncommon luck to be there when it happened. I leave it to others to present a balanced and documented history; this is what I remember.

I selected Paul Hubbard as my thesis advisor at the University of North Carolina, despite the warnings of my fellow graduate students that NMR had nothing interesting in its future. Professor Hubbard had studied under Edward Purcell. In fact, until the arrival of MRI, everyone working in NMR could trace his or her academic lineage back to either Purcell or Bloch, the originators of NMR.

The Physics Department of the University of Nottingham was very active in NMR when I went there as a postdoc in late 1971. Its reputation in the field was due to Professor E. Raymond Andrew, the department chairman. As I worked with him, we searched for biological applications of NMR. We used NMR to study the properties of crystalline amino acids. Others, at Nottingham and elsewhere, were looking at the NMR properties of animal tissue. Bill Derbyshire at Nottingham was looking at the relaxation times of fish muscle to determine, among many other things, if a violent death affected its NMR properties and its taste. Professor Andrew showed me a short article describing relaxation measurements of a tumor on the tail of a mouse. As I remember, they had dropped the small tumor, while still attached to the live mouse, into a standard NMR spectrometer. This paper, and an earlier paper arguing that T_1 could be used to diagnose cancer,¹ did not suggest any useful application to us since we saw no way to make organ-specific measurements in humans without removing the tissue.

In 1973, during one of the religiously observed free-discussion times known as morning coffee and afternoon tea, Peter Mansfield mentioned that he wanted to apply a strong enough gradient to a solid to resolve the interaction between adjacent spins. We discussed what other applications such a technique could have since the NMR spectrum in the presence of a gradient reflects the distribution of the sample along the direction of the gradient. We tried, without success, to come up with biological applications for looking at one-dimensional distributions.

Later in 1973, I attended an NMR meeting in Krakow, Poland. At the meeting, Mansfield presented a short paper that contained three separate ideas. One was the suggestion of applying a strong gradient to show crystal structure in one dimension. John Waugh of MIT stood up during the question period and asked Mansfield if he knew of Paul Lauterbur's recent paper² which presented the idea of using NMR to form images. This work was unknown to both Mansfield and me and, as far as I could tell, everyone else in the audience.

I did not spend much time thinking about Lauterbur's idea until hearing him lecture on the subject at an NMR meeting

in Bombay in January 1974. After his lecture, I went up and introduced myself. His enthusiasm for the idea was infectious.

The paper I presented at that Bombay meeting described spinning the NMR sample very rapidly in order to reduce the broadening of the spectral lines. As part of this work, I had been looking at the various broadening mechanisms, including that of externally applied inhomogeneous fields, or gradients. A passing idea was to keep the sample stationary and 'spin' the gradient in order to narrow the spectral lines. This was the basis of the early 'sensitive point' method of imaging. Rotating the gradients allows the portion of the sample on the axis to experience a static field while the remainder of the sample experiences an oscillating field. Applying another oscillating gradient in the direction of this axis made the field oscillatory everywhere except at one point. By properly applying the rf field, you could saturate the spins everywhere except at that one point. Then by scanning this point through the sample, it would be possible to obtain an image. Rapid and rock-steady rf pulses are applied. The pulse amplitude is adjusted for maximum signal strength, which usually occurred at less than 90°. The signal refocuses and forms an echo that peaks at each rf pulse. This interesting rf technique is called 'steady-state free precession'.

I flew back from Bombay with Bill Moore, a member of the Nottingham Physics Department. He and I passed the time by discussing moving gradients as a way of localizing the magnetic resonance signal. By the time the long flight was over, the ideas were well enough formulated to allow some laboratory work to start.

One constraint we had in developing an imaging method was the lack of a computer. I did have access to Andrew's pulsed NMR spectrometer, which had an analog output—and everything else in the lab was analog. I spent evenings and weekends assembling clock motors and potentiometers and coils. Bill provided constant encouragement. By April of 1974, we had produced the first images. With this work, we were the first group after Lauterbur to produce magnetic resonance images. Bill and I applied for and were awarded the first patent on MRI or, as we called it then, 'NMR spin-mapping'.³

During this time (in 1974), my good friend Al Garraway, a postdoc with Peter Mansfield, would stop by my cubicle after morning coffee and ask all sorts of questions about how to do imaging, what the problems were, etc. Then, suddenly, he stopped asking. I learned later that he had started working on MRI in his laboratory. He applied weak rf pulses in the presence of a field gradient in order to achieve spatial selectivity.

Next door to where Al was working, Mansfield and another of his postdocs were quietly developing a related method. They were attempting to saturate all of the sample except for the selected region of spins. As I understand the story, one day Mansfield showed Garraway a manuscript, or patent application, that he had prepared on his work. Garraway showed him what he had been doing. The issue was finally resolved by combining both efforts in the patent and publications.

In late 1974, I accepted a position with Professor Irving Lowe at the University of Pittsburgh. During my stay there, Professor Andrew and Bill Moore applied for and were awarded a grant from the Medical Research Council to develop an NMR imaging system. So I returned to Nottingham and, for the next couple of years, worked flat-out to put together

Figure 1 Participants at the First International Meeting on Magnetic Resonance Imaging, University of Nottingham, April 1976

an imaging system for 3-in. diameter samples. I remember working the usual 12 h one Christmas day. Every computer instruction, including, for example, those for handling the cassette tape drive, was loaded by hand using a set of toggle switches on the front panel of the Data General minicomputer.

As initially configured, the system used a sensitive line, as described above. A static gradient was applied along the line and then the signal was Fourier-transformed to obtain the distribution of the sample along the line. The steady-state free precession pulse method produces a comb of discrete spectral signals. The data collection and Fourier transformation are done so that each point in the transformed spectrum corresponds to one of the discrete signals. The sensitive line was swept slowly through the sample to form an image of a slice of the object.

At the beginning of the project we considered using several different magnets, including permanent magnets, superconducting magnets, and resistive electromagnets. We chose a then current Varian iron-core electromagnet with modified pole faces that gave us something like a 3-in. diameter working volume.

Early in the project, Neil Holland joined us. He later became the principal NMR scientist and engineer for Picker. Paul Bottomley joined the effort as a Ph.D. student. He later became an important scientist in the NMR imaging effort of General Electric (GE). Peter Allen, a member of the Physics Department staff, became active later in the project.

Professor Andrew organized the first international MR imaging meeting at Nottingham in April 1976 (Figure 1). Earlier scientific meetings had included presentations on MRI, but this was the first meeting dedicated exclusively to the subject. All of the groups working on MRI projects, with one exception, were represented. Although important work was being done in applying NMR to biological problems, it was not included in this meeting.

- Paul Lauterbur, the originator of the field, was there.
- Richard Ernst was there—his major contribution to imaging had occurred the previous year.
- Jim Hutchison was there. He was developing a small and very innovative whole body imaging system at the

University of Aberdeen. I always enjoyed talking to Jim; he always had good ideas. Once, when I visited his lab, Bill Edelstein, who would later go to GE, was there. The personality difference between Jim and Bill was so great that it was difficult to get a chance to listen to Jim.

- Peter Mansfield and his students Andrew Maudsley, Ian Pykett, and Peter Morris were there.
- Hugh Clow from EMI was there. Under his direction, the EMI engineers put together an imaging system with a magnet and coils large enough for imaging the human head. There was no one in his initial group who knew NMR. When they turned the system on, no image appeared. After obtaining advice from some Nottingham scientists, they produced the first image of the human head using the original Lauterbur method.
- Locher and Creighton, who were working with Philips, were there.

Bottomley, Holland, and I wrote up and published the initial results from our work.⁴ That issue of *Nature* had a cross-sectional magnetic resonance image of a lemon on the cover. The article, which contained a clear thin-slice image through Bottomley's wrist, was important in that it provided the first convincing evidence that MRI would become clinically useful.

As a result of the increasing stress between the different imaging groups within the Nottingham Physics Department, and since the goal of the MRC grant had been achieved, I left Nottingham to accept a position with GEC Medical outside London. After several months of trying to get an MRI program started, I resigned and began a long and fruitful association with the Harvard Medical School, The Massachusetts General Hospital, and the Johnson & Johnson company.

Jack McConnell was an executive with Johnson & Johnson and was responsible for finding and evaluating new technology for the company. He came to Nottingham to visit us during the very early days. It was never clear what Jack was trying to do, but I came to believe that he made at least a partial attempt to gain control of the emerging technology for Johnson & Johnson. He also placed an order with Oxford Instruments for a superconducting magnet suitable for MRI of a human in late 1977 or early 1978. After

resigning from GEC, I became a consultant for him, starting in late 1978, and helped establish the specifications for the magnet. We requested a superconducting magnet with a 1-m diameter room-temperature bore and an operating field of 1.8 T. However, the specifications, which were accepted by Oxford Instruments, were too ambitious. It would be several years before Oxford Instruments could build such a magnet.

At about this time I received a visit from what I came to think of as the 'gang of four', Gerry Pohost, Joanne Ingwall, Mark Silverman, and Eric Fossel. Enabled by their friendship and support, I returned to the USA in the late fall of 1978 and accepted a position with Juan Taveras, head of the Radiology Department at the Massachusetts General Hospital (MGH). For the next year, with the full support of the 'gang of four', I worked as a facilitator in negotiating a technology development agreement between MGH and Johnson & Johnson. The negotiations included the heads of the departments of surgery, radiology, cardiology, internal medicine, and neurology on one side, and Jack McConnell on the other. The successful agreement was, I understand, the first of its kind for the Harvard Medical School system in that it exchanged access to intellectual property developed within the program for significant financial support. Since that time, other and much larger agreements of the same type have been put in place with other companies.

During that year, the initial steps were taken at the MGH to establish the Society of Magnetic Resonance in Medicine. Gerry Pohost was the initial driving force. Joanne Ingwall, Paul Lauterbur, and later Tom Budinger worked closely with him. I was on the initial board of directors and was head of the program committee for the second annual meeting. I remember discussions about which radiologist to invite to be on the board. The society has been very successful and influential in promoting the technology and it currently has about 4000 members.

After the MGH and Johnson & Johnson agreement was in place, it became clear that the hospital environment was not ideal for developing a complex imaging system. So, in late 1979, I moved to Solon, OH, and began working within Technicare (a recently purchased and wholly owned subsidiary of Johnson & Johnson) while retaining my appointments at Harvard and MGH. I expected to return to the MGH with the initial system to explore clinical applications. However, the development program at Technicare acquired such momentum that I never did go back.

During those early days, not many groups were working on MRI. We all knew each other, liked each other, and enjoyed sharing ideas. The first US meeting dedicated to MRI was hosted by the Vanderbilt Radiology Department in Nashville. The second meeting was at the Wake Forest Medical School in North Carolina. The list of attendees gives a clear picture of who was interested in the subject at the time.

In late 1980 and early 1981, a few of us from Technicare flew to England (on Concorde) to negotiate with Thorn EMI for the purchase of their MRI program. This group was in the process of installing a whole-body 0.3 T system in the Hammersmith Hospital. At the time we were there, the system was beginning to produce images of the head. On our third trip there, they told us that they had already done a deal with someone else.

At about the same time, we visited Leon Kaufman's lab in South San Francisco. His MRI work had been funded until

then by Pfizer, but they had decided to get out of the business. I urged the Technicare management to 'buy' the group. Just after we made an initial visit, we learned that they had become associated with Diasonics and were no longer available.

Technicare was a very aggressive engineering-driven medical imaging company and was the ideal environment for the rapid development of an MRI product. We put together a team of about 14 engineers and, within 9 months, had a small system producing images at 1.5 T. We had the mistaken idea that it would be easier to develop a small system first. We also wanted to explore as early as possible the clinical utility of spectroscopy. This 'small animal' system went to the MGH and enabled the team there to publish several early papers.

Our initial two-dimensional imaging method used steady-state free precession together with oscillating gradients to select the slice and back-projection to obtain the two-dimensional image within the slice. (One of the many invaluable inputs from the MGH group was that the motion sensitivity of this method was too great for most clinical applications.) Another early method used three-dimensional back-projection with reconstruction of slices in any desired orientation after the data were collected. This three-dimensional acquisition had the advantage of simplicity. The reconstruction kernel, or the back-projection filter, was localized, unlike the filter for two-dimensional back-projection. Also, rapidly switched gradients were not required. We felt that, since the new technology was inherently three dimensional, it would pay to exploit its strength. However, radiologists preferred the images that could be obtained from a set of separately acquired slices. So we soon began using selective irradiation to define the slices and, within the slice, phase and frequency encoding followed by a two-dimensional Fourier transform to obtain the image.

We put together systems using the best magnets we could obtain. We had a standing order with Oxford Instruments to send us their latest and best magnet. The first large magnet from them was a whole body resistive water-cooled magnet operating at 0.15 T. They shipped it full of cooling water which froze while crossing the Atlantic. We had to pull it apart and machine out the split copper water pipes that were embedded in the aluminum plates. Within a few days, we had it reassembled and working.

Later, we designed, manufactured, and shipped several of our own water-cooled whole body magnets using a quite different design. The first one went to the MGH and was used there for several years. These first resistive systems had just two imaging modes, called 'a' and 'b'. At the early users-meetings, the first clinical users thoroughly enjoyed debating which mode was best. Then, in about 1983, we gave the user the ability to design his own protocol, to select the slice thickness, slice spacing, pulse timings, and the like. This innovation perhaps loaded too much responsibility, and even confusion, onto the radiologists.

We soon accepted delivery of Oxford Instruments' first whole body sized superconducting magnet. We built systems based on 0.3, 0.5, and 0.6 T (and, much later, 1.5 T) superconducting magnets. They were able to get their first meter-bore superconducting magnet only up to 0.3 T and, even then, it went through repeated quenches to get there. We continued to push for higher fields and insisted that we receive every magnet they built. After shipping us two or three at 0.5 and 0.6 T, they came to us and said the next one would go only to 0.35 T. After considerable internal discussion, we decided to

reject it. It probably is a coincidence that Dasonics introduced its product at 0.35 T.

Technicare made a big product announcement and introduction of resistive and superconducting systems at the 1981 RSNA (Radiological Society of North America), the huge annual meeting of radiologists. The product we introduced there, the Teslacon, was listed by *Fortune* magazine as a 'Product of the Year'.

My experience was with only one of the teams that developed the early systems. I assume the other teams were similar. It was a very exciting time, and we saw the inside of humans in a brand new way. For example, we saw the first sagittal slices of the human brain, the view of the brain that is now everywhere. We saw clear tumors and radiation damage in the brain of the first patient we put in our prototype system. We worked flat-out, adding features, solving problems, and immediately installing our improvements in the systems being used on patients.

John Keller and Russ Compton were the principal engineers. Each of them was more productive than any other ten people I know. David Kramer and Hong Yeung were the principal scientists. They, and their key team members, were trained as chemists. The chemists and the engineers worked well together. While physicists incorrectly view themselves as 'super' engineers and insist on being involved in designing the system, the chemists were interested only in its performance.

We were significantly ahead of the academic groups. We would go to meetings and be quietly amused as the academic groups took credit for techniques and ideas that we already had in use with patients. As a result of this experience, I have wondered how often a new technology was actually developed within a company even though history has it being developed within academia.

We did not publish in the scientific literature; we were having too much fun and were too busy. Furthermore, despite the wise and persistent requests of the Johnson & Johnson management, we did not patent much of what we did. Prior to MRI, the tradition among the medical imaging companies was for each company to obtain a few patents and then quietly to ignore everyone else's patents. None of the players wanted to start a patent war. Battles are now being fought, however, over some of the early patents.

We developed a lot of new technology. Even though it serves no purpose to try to list it here, I will mention a couple of things we worked on. We looked at all sorts of ways, including spirals, to move around in k -space during data collection. We looked at rectangular back-projection. We developed many innovative pulse sequences (including interleaving, multislice, and multiple echo), sequences with the higher moments balanced for motion compensation, half Fourier acquisition, flow and chemical shift imaging, fluorine imaging, and the like. We built all our own hardware, including the complete acquisition system, data handling and reconstruction hardware, gradient power supplies, and a solid low-noise potted gradient coil with distributed windings. Some of the first special-purpose rf coils we developed were for breast imaging.

We kept the early customer shipments as quiet as possible. We did not want to frighten our competitors. We manufactured and placed perhaps about 15 systems before receiving clearance from the US Food and Drug Administration (US FDA) to market the products. Technicare and Dasonics

received the first clearance at the same time. The submission to the US FDA was based on clinical data obtained from the 0.15 T system at the MGH, and the higher field systems operating in Cleveland. We worked closely with the US FDA to help them understand what to worry about and how to evaluate a system.

On 9 April 1986, Johnson & Johnson announced that Technicare was closed. The engineering team was in the early stages of a major upgrade to the magnetic resonance product. We were allowed to finish the upgrade. We collected a team of 270 of the best people from throughout the company, finished the project, and handed it over to a GE manufacturing team by the end of the year.

By the end of 1986, MRI was a well established and growing business.

POSTSCRIPTS

Many of the scientists contributing to MRI have been publicly recognized. However, those who have quietly turned the scientists' ideas into products, products that significantly improve the quality of our health care, have not been recognized. Those without recognition have been working within companies—the engineers, manufacturers, and businessmen. To a large degree, the development of MRI as a clinical reality is due to businessmen with vision.

Although individuals in several companies deserve credit, my interaction was with Technicare and Johnson & Johnson. Joe Teague, President of Technicare, and J. B. Richey, Head of the Technicare's New Ventures Division, provided the unique and necessary environment for rapid product development. Jim Burke, Chief Executive Officer of Johnson & Johnson, had the remarkable vision and bravery to pour substantial money into a development program that had great promise but no guarantee. I believe Burke deserves credit for making MRI a clinical reality. Without the early effort of Technicare, the other companies may not have made the commitment to invest the required resources to take the technology out of the lab and into the hospitals.

No discussion of the early days of MRI would be complete without mention of Raymond Damadian. Unfortunately, any mention of Damadian creates controversy. Damadian's belief that T_1 and T_2 measurements could be used to detect cancer may have motivated several people to take MRI more seriously than they otherwise would have. However, I believe that his idea did not affect the development of the field of MRI. Nothing could be done until Lauterbur showed how gradients could be used to make images, and once that was done, Damadian's early observations did not affect anyone's actions. Furthermore, as far as I know, no one has ever detected or diagnosed cancer by measuring relaxation times. Damadian was invited to present his work at the first one or two MRI meetings in the USA. At those meetings, he astonished the attending scientists by showing a slide of his patent on detecting cancer⁵ and disclosed little about his research efforts.

The one person who came up with the fundamental idea that is the basis of MRI is Paul Lauterbur. His publication² was the first to suggest MRI, and in fact described it adequately enough for someone 'skilled in the art' to do it. The publication clearly states the potential clinical applications. It is unusual

for the initial publication in a new technology to be so clearly identifiable.

In addition to making the seminal invention, Lauterbur was tireless in advocating MRI. He nurtured the field until it attained a life of its own. He visited our lab several times while I was working in England. He paid for me to visit his lab in Stony Brook. He was open with his ideas and full of encouragement. He made sure, through these efforts, that the early developers stayed in touch and were friends.

Once, in an intemperate moment (Paul and I used to enjoy our intemperance whenever we got together), I asked Lauterbur why he did not obtain a patent. His article in *Nature*,² with a little work by a patent attorney, would have been the controlling patent for the entire field of MRI. He

clearly suffered as he told me that the university bureaucracy got in the way and, in fact, maintained that such a patent would have no value.

Hoult, D. I.: Biomedical NMR Instrumentation—A Personal Viewpoint

D. I. Hoult

Institute for Biodiagnostics, National Research Council, Winnipeg, Canada

INTRODUCTION

The problems facing the researcher who attempts to cross disciplinary boundaries can be quite daunting. Not only is there a new vocabulary to be learnt, but new lore, concepts, and even thought processes often conspire to present a considerable barrier to the interloper. Equally, the analytical tools and knowledge that one carries into a new arena may be objects of incomprehension and even suspicion by the local residents. Communication becomes of paramount importance; patience and respect valuable commodities. However, in 1968, with a new degree in physics, and a passionate interest in electronics—I was an amateur radio enthusiast—I knew nothing of such subtleties as I started my doctoral studies with Professor (later Sir) Rex Richards in the Physical Chemistry Department at Oxford University. I was initially to investigate the subject of field homogeneity, a topic that has exercised me on and off ever since, but a year later, when he announced his intention of resigning the professorship and moving into the Biochemistry Department, I had learnt enough to be, along with the rest of his research group, apprehensive. I was being marched from *terra externa* into *terra incognita* and was not sure I liked it.

Probably partly out of reaction to an alien environment and partly from a need completely to understand a subject to feel secure therein, I delved very deeply into the instrumental requirements of the then-new technique of Fourier transform (FT) spectroscopy. With my expertise in electronics, I felt on safe ground there and Rex, as was his wont, gave me free reign. Biochemistry passed me by and I put all my efforts into helping build the best quadrature FT spectrometer that we could. As my understanding increased, I was able fairly easily to cope with problems such as receiver deadtime, dynamic range, and radiofrequency (rf) leakage, but two difficulties loomed large: how to improve the sensitivity of our 7.5 T superconducting instrument, and how to remove ‘ghost’ lines in a quadrature spectrum caused by imperfect quadrature detection.¹

SENSITIVITY AND CYCLOPS

In the early 1970s, the theory of NMR signal reception was rooted in continuous wave (CW) spectroscopy performed with resistive electromagnets. Thus the emphasis was upon absorption of rf energy by a sample in a solenoidal receiving coil, and of particular importance was the ‘filling factor’ of the coil. Strictly speaking, if a current I is passed through a coil of inductance L so that magnetic energy $E = LI^2/2$ is

stored therein, the filling factor η is the ratio of the energy E_s stored in the magnetic field passing through the sample, to the total stored energy, i.e. $\eta = E_s/E$. However with a solenoidal coil it can be shown that about half the energy is consistently stored within the confines of the coil, regardless of its exact winding details. Thus the term ‘filling factor’, as the appellation implies, came to be understood as half the fraction of the space inside the receiving coil occupied by the sample. However, when I applied formulas developed by my predecessor in the group, Dr. Howard Hill, to the probes I had built, I consistently obtained predictions of signal-to-noise ratio that were two to three times too large.

To my chagrin, I later discovered that my error was in using the popular, rather than the exact, definition of filling factor, and this mistake alerted me most forcefully to a danger ever-present in science—that of applying a well-known and trusted theory to a situation that is subtly different from that envisaged by the proponents of the theory. A superconducting magnet employs of necessity a saddle-shaped rather than a solenoidal receiving coil, and the open geometry ensures that the fraction of the magnetic energy stored in the confines of the sample is heavily dependent upon that geometry. For example, if a very thin conductor is used, most of the energy is stored round the conductor and the filling factor can be as small as 0.05. I now believe that the way to avoid making such mistakes is to take the time and effort to understand a subject, *on one's own terms*, from the most fundamental level upwards. With my failure to explain the observed signal-to-noise ratio, I was forced to ask two very basic questions: from whence comes the signal and from whence the noise? The respective answers were simple but revealing: from electromagnetic induction of a voltage in the receiving coil, caused by the precessing nuclear magnetic moments (i.e. an alternator!), and from the generation of random voltages—a measure of which was the coil's resistance—by Brownian motion of the coil's electrons. The rest of the paper that Rex Richards and I wrote on the subject is an embellishment of these two principles—the consequence of a new view taken *de profundis*.^{1,2} The ideas of quadrature detection in the laboratory frame with two receiving coils to increase the signal strength, and of lowering the temperature of those coils to decrease the Brownian motion,¹ came as a natural consequence of that new view. The former has found extensive use in imaging, while Styles and colleagues have demonstrated with elegant engineering how profitable a probe temperature reduction can be for ¹³C spectroscopy.³

The solution to the problem of quadrature ‘ghosts’ came about in a different manner. I understood the difficulty completely, but was at a loss as to how to resolve it. For example, the gains of the two outputs X and Y of a quadrature receiver might differ, and exaggerating the error we might write for the two free induction decays (FIDs):

$$X_0 = 1 \cos \omega t \exp\{-t/T_2\} \quad (1)$$

$$Y_0 = 0.9 \sin \omega t \exp\{-t/T_2\} \quad (2)$$

or

$$X_0 + iY_0 = [(1 + 0.05i) \exp\{i\omega t\} - 0.05i \exp\{-i\omega t\}] \times \exp\{-t/T_2\} \quad (3)$$

where $i = \sqrt{-1}$. From equation (3) it is clear that in addition to a small change in the main signal, a ‘ghost’ term with frequency $-\omega$ is introduced by the error.

I prowled round the problem trying to probe it from various angles, and among the many possibilities I explored was that of averaging: whether there was any way to generate from equation (1) and equation (2) two signals that each had an amplitude of 0.95. I could find no simple method, but dealing with quadrature detection the idea of a 90° phase shift was never far away, so it was perhaps not surprising that I also considered the consequence of changing the transmitter phase by 90° . This gives two new signals:

$$X_{90} = 1 \cos(\omega t + \pi/2) \exp\{-t/T_2\} = -\sin \omega t \exp\{-t/T_2\} \quad (4)$$

$$Y_{90} = 0.9 \sin(\omega t + \pi/2) \exp\{-t/T_2\} = 0.9 \cos \omega t \exp\{-t/T_2\} \quad (5)$$

and I immediately saw that I could realize my idea of averaging, for:

$$(X_0 + Y_{90})/2 = 0.95 \cos \omega t \exp\{-t/T_2\} \quad (6)$$

$$(Y_0 - X_{90})/2 = 0.95 \sin \omega t \exp\{-t/T_2\} \quad (7)$$

The combination regenerates perfect quadrature signals. Generalizing the idea, it was found that errors of quadrature phase were also corrected, while the accuracy of correction was insensitive to the precision of the transmitter phase shift. Thus was born CYCLOPS,¹ a CYCLically Ordered Phase Sequence in which the phase of successive transmitter pulses, and hence of FIDs, was incremented by 90° , while the computer was used to perform the ‘data routing’ and averaging of equation (6) and equation (7). My approach in this instance could not be dignified with any Latinism—it resembled more a ‘search and destroy’ mission in which I boringly and systematically explored possibilities.

POSTPRANDIAL SERENDIPITY AND SLICES

The top floor of the Biochemistry Department commands a fine view of Oxford’s ‘dreaming spires’ and its library and common room are situated there. It is the custom for work to pause at about 3.45 p.m. for tea, biscuits, and the view, and one day in 1974 my colleagues (in particular, David Gadian) and I were so doing while chatting with members of George Radda’s biochemistry group (in particular, Steve Busby and John Seeley). At that time, our spectrometer was tuned to ^{31}P NMR to observe phospholipids and to our surprise we discovered that the biochemists were assaying phosphorus in excised rat muscles by a mysterious technique that sounded vaguely reminiscent of a medieval torture—‘freeze clamping’. Naturally, the thought occurred to everyone that it might be possible to observe phosphorus metabolites by NMR. I knew that our instrument could detect phosphorus in 0.5 mM solution and so was enthusiastic concerning our chances

of detecting metabolites in the millimolar range. David and John became equally enthused, but enthusiasm waned when the thought arose that a muscle would spoil the field homogeneity. I disagreed strongly and remember remarking that the homogeneity would be fine so long as the muscle was in water. (About the only thing I knew about muscle was that it was mostly water!) John quickly doused the proposal, objecting that the muscle would have to be bathed in Ringer’s solution. I had no idea what Ringer’s solution was, but hearing the magic word ‘solution’ and knowing that the susceptibility of most liquids was similar to that of water I pushed very hard for the experiment to be done. David and John went off to work out the details; I surreptitiously went to the library to discover what on earth Ringer’s solution was, and realized that I was going to have to learn at least a little biochemistry. I descended to the laboratory to my first encounter with rats. I expected gore but not the smell, and noticed that I was not the only one to leave the room quite frequently. In honor of the occasion, David had selected a new 8 mm NMR tube, and a hind leg muscle was inserted together with the solution. The result is a well-known paper in *Nature* that heralded the field of in vivo spectroscopy.⁴ Less well known is that the paper was at first rejected by the referee on the grounds that ^{31}P NMR was not novel, and that the experiment failed the second and third times. The failure was traced to the use of old NMR tubes that had been re-cut, and had in consequence rough edges that scratched the muscles as they were inserted. Various theories, ranging from induced contraction to release of enzymes, were put forward to explain the failure but were not explored; there was too much success in the air.

This was my first encounter with serendipity in science and I have often dwelt since on the wisdom of having new NMR tubes, communal tea breaks, small conferences in relaxed surroundings, and the urgent need for a modicum of interdisciplinary education. In retrospect, our progress into the world of biochemistry would have been much more rapid if we had had some basic formal course work therein.

Not surprisingly, ‘my’ instrument was soon lost to me, inundated with biological experiments, and in particular David Gadian started a very fruitful collaboration with Doug Wilkie and Joan Dawson of (then) University College, London. However, I felt bereft, and having read Paul Lauterbur’s classic paper in *Nature*,⁵ was intrigued with the prospect of imaging animals and people. My interest became urgent when I read in short order papers by Lauterbur and Garroway concerning pulses for slice selection, and realized with intuitive certainty that they were wrong!¹ For me, that realization remains a classic example of how a different viewpoint can lead to radically different understanding and interpretation. The two papers described how in a sample whose spectrum was broadened by a field gradient a long, low-power pulse could selectively flip on-resonance magnetization, supposedly giving thereby signal only from those spatial regions (a slice) whose frequency was not significantly disturbed by the gradient.

However, I viewed the experiment differently. I saw the spectrometer as a ‘black box’ with transfer function $H(\omega)$ (the spectrum) into which one fed a time-dependent driving function $T(t)$ with a certain spectral density function $T(\omega)$ (the selective pulse), and from which there issued a time-dependent output $S(t)$ (the NMR signal) with spectral density function $S(\omega)$ determined by $T(\omega)$ and $H(\omega)$. In other words, assuming

to a first approximation a linear response theory:

$$S(\omega) \approx H(\omega)T(\omega) \quad (8)$$

But, I reasoned, when a strong field gradient is applied to a sample such as a tube of water, the spectrum $H(\omega)$ is essentially flat over a large bandwidth; in other words, $H(\omega)$ can be assumed with good accuracy to be a constant h . Thus:

$$S(\omega) \approx hT(\omega); \quad S(t) \propto T(t) \quad (9)$$

and the spectrometer functioned in effect as a very expensive attenuator, the output $S(t)$ being a small replica of the input $T(t)$. However, in contrast to an attenuator, an NMR instrument is turned off when the transmitter is on, and I therefore felt that the only signal one should see should be due to the breakdown with large flip angle pulses of the linear theory of equation (8). To prove my point experimentally, I set up a simple on-resonance experiment with a sample of phosphoric acid. (There was no chance of using another nucleus by this time!) With a homogeneous main field, I applied a 2 ms 30° pulse, thereby keeping the experiment in an approximately linear regime, and obtained a strong, on-resonance FID of known phase. I then applied a field gradient with the z shim and watched the signal become shorter and shorter as I turned the potentiometer until its duration became less than the dead-time of the spectrometer—it disappeared. Not surprisingly, I discovered that a signal, a mirror image of the pulse, could be recovered with the aid of an echo, and thus was born the slice selection technique that is in common use in imaging. Having studied the nonlinear properties of the NMR system for inclusion in my doctoral thesis, I was not surprised to discover that a small *negative* FID followed a 90° selective pulse and that a large negative signal followed a selective 180° pulse—presumably the signals seen by Lauterbur and Garroway. However, while I proved my point experimentally fairly easily, a mathematical proof took me considerably longer, and as a result controversy raged for some time. Incidentally, the engineering and rotating frame points of view are easily reconciled when the *phases* of the flipped isochromats are taken into account.

IMAGING

Some months later, Paul Lauterbur passed through Oxford and we had an enjoyable discussion about spinning samples during which he produced the aphorism that ‘nuclei are slippery little things’ and do not change their angular momentum just because the sample does. I explained to him my ideas concerning the origins of the signal-to-noise ratio and how I felt they could be extended to formulate a theory for imaging. I also showed him my results concerning slice selection. When I had finished he looked at me quizzically and, imitating my British English, said ‘You’re telling me I’ve been a bloody fool!’ I think I blushed from head to toe as I miserably said ‘Yes’. He pondered the arrogance of a young postdoctoral researcher and then suggested a collaboration on imaging sensitivity.

Again the black box concept was useful as I envisaged measuring resistance to predict the Brownian noise. If all an

engineer had available to him were two terminals projecting from a black box wherein was a large coil, he would measure the resistance indirectly from measurements of Q factor and inductance. If, unbeknownst to him, a person’s head were then placed in the coil, all he would notice would be a sudden change of Q factor, which he would interpret as increased resistance r_m and hence increased noise (originating from the Brownian motion of electrolytes in the human body). Thus, I realized it was possible to extend my theory of signal-to-noise ratio simply by calculating the additional resistance r_m . The task was relatively simple for regular shapes and we were both pleased with the resulting theoretical paper,^{1,6} but less pleased when we had heard nothing from the journal many months after submission. The paper had disappeared in the mail and was eventually published much later than we had hoped.

It was clear that *in vivo* spectroscopy would be the dominant NMR topic for many years in the Oxford Biochemistry Department, and as I was by now thoroughly ‘hooked’ on imaging, I moved at Ted Becker’s instigation to the National Institutes of Health (NIH) in Maryland in 1977. I was determined that I would not ‘lose’ another machine that I built and so, with the complicity of Ching-Nien Chen who came to me as a postdoctoral worker from Lauterbur’s group, the imaging system for babies that was conceived there never quite came to gestation. Instead, it served as a test-bed for ideas such as shimming an imaging magnet with pieces of steel. In the early days of imaging there was considerable fear that the slightest amount of steel in the environment could wreck the magnet’s field homogeneity. However, there was little hard information on how serious the problem was and we attempted to gain some by placing steel plates at various distances from our magnet. It was clear that the field generated by any steel’s magnetization could, as usual, be analyzed in a spherical harmonic basis set. The problem was to quantify the effects and assign amplitudes to the harmonics. Working with a French mathematician, Françoise Roméo, who was a guest in my laboratory, we realized that the mathematics were tractable for elementary volumes of magnetized steel, provided we knew the direction of the field at those volumes, but that a full computation for an arbitrary volume and location was much more difficult. However, when one remembers that if steel *is* present, one’s primary objective is to remove its deleterious effects, it was but a short conceptual step to the realization that elementary volumes could be placed *inside* the magnet to perform this task. There, they would saturate in a strong, known field of given direction z and would generate accurately quantifiable fields—which could be used to cancel fields produced by steel without. We could fight steel with steel! We tested the idea on our home built baby system with ball bearings and cut plate, and along with a review of field correction techniques sent the results to the fledgling *Magnetic Resonance in Medicine* for the first issue.^{1,7}

A severe test of the method, that resulted in its adoption by industry and the overturning of objections to NMR units being sited within hospitals, came a little later when a commercial imager was installed in the NIH Radiology Department. The weight of the whole-body, superconducting magnet was taken by a strengthened steel I-beam in the floor which reduced the homogeneity to 1.2 parts per thousand: the specification was 10 ppm. The magnet manufacturers had attempted to shim the magnet with over 400 kg of steel on the outside, and to

the consternation of many, Picker engineer, Dooley Lee and I stripped it off. So began three weeks of frantic activity, shimming the magnet not with elementary volumes of steel within—they were too weak—but with steel rods of various shapes and sizes for which we scoured half of Maryland. The theory developed as we progressed,¹ but finally with about 10 kg of steel we obtained the desired specification in a systematic manner, though not without drama. We were both very tired towards the end of the exercise, and one morning while carrying a steel rod I tripped and fell. Poor Dooley was kneeling in the magnet and the rod flew with great speed and precision directly between his legs without touching him. I thought he was going to pass out in the magnet from shock!

CONCLUSION

NMR imaging and in vivo spectroscopy are now mature topics from the point of view of instrumentation development. However, NMR has provided exceedingly fertile ground for transplanted physical engineers such as myself, and will

hopefully continue to do so. The complexity and diversity of this 50-year old tool leave room for fresh viewpoints and continue to challenge understanding and ingenuity. My fear is that because it *is* a mature topic, the continuing need for instrumentation research in an academic environment will neither be recognized nor catered for financially. Much has been accomplished; much remains to be achieved.

Hurd, Ralph E.: A Brief History of Gradients in NMR

Ralph E. Hurd

GE Medical Systems, Fremont, CA, USA

The history of field gradients in NMR begins in 1950 with Hahn's treatise on spin echoes.¹ This work described the relationship between echo intensity, molecular diffusion, and spatial variations in B_0 . The measurement of molecular diffusion is improved by the introduction of a static field gradient coil as described by Carr and Purcell in 1954.² Only a year later, Anderson et al.³ reported the first application of pulsed field gradients. This article introduced the idea of using a gradient pair to avoid spurious echoes from imperfect rf refocusing. Gradient selection of stimulated echoes was also described. These early pulsed gradient applications are still used in contemporary NMR, especially in imaging and localized spectroscopy, where they have taken on names such as *primer-crusher pairs*, *crushers*, and *spoiler* gradients. Oddly enough, this was one of a pair of papers in 1955 that focused on the potential for NMR-based storage memory. In the other, Fernbach and Proctor⁴ used a static gradient to encode and read out the frequency response from selective rf excitation. Over the next 10 years little progress was made toward routine use of gradients in NMR. Almost a notable exception is a 1960 epistle to the geophysics community in which Hahn described the potential use of gradients to encode coherent motion—the velocity of sea water.⁵ A major advance came in 1965 with Stejskal and Tanner's introduction of pulsed gradients for the measurement of molecular diffusion.⁶ In a 1968 paper which marks the rebirth of interest in gradient methods unrelated to motion, Vold et al.⁷ extended the use of spoiler gradients to avoid the effects of imperfect rf inversion. Shortly thereafter, a number of groups reported the benefits of using spoiler gradients, often referring to them as *homospoil pulses*.

The use of field gradients to obtain images, as first demonstrated by Paul Lauterbur in 1973,⁸ led to profound changes in the history of gradients and in the development of NMR. In 1974, Garraway et al.⁹ reported the use of tailored rf in the presence of a gradient for slice selection. As with the development of the diffusion measurement, NMR imaging was first accomplished using static field gradients. The use of pulsed gradients for imaging followed quickly as described by Kumar et al. in 1975 for Fourier imaging¹⁰ and by Mansfield in 1977 for echo planar methods.¹¹ The spatial selectivity of most modern MRI uses a combination of frequency encoding, phase encoding, and slice selection. With a few exceptions, the development of localized spectroscopic methods has followed in the footsteps of imaging. In addition to their spatial encode function, the use of gradients to avoid artifacts is an ubiquitous part of MRI and in vivo spectroscopy. The important applications of flow and diffusion imaging use gradients to encode both space and motion, and have developed in sophistication along with the rest of MRI.

In 1977, Wokaun and Ernst¹² described the relationship between coherence order and the effect of a gradient pulse. The

idea of using gradients for coherence pathway selection was further developed in several key papers.^{13–16} In early studies, the potential benefits of using pulsed gradients were often overshadowed by drawbacks such as long gradient recovery times, increased phase instability, peak shape distortion and for high-resolution applications, disturbance of the field/frequency lock system. Preemphasis and improvements in gradient amplifiers helped, but the development that had the biggest impact was the introduction of actively shielded gradients.^{17,18} This was important for the development of imaging and localized spectroscopy, especially on small horizontal bore systems equipped with maximum diameter gradient coils. For us, the inspiration to pursue high-resolution applications of shielded gradients came from surprisingly undistorted in vitro results used in the development of in vivo lactate imaging.¹⁹ The work that led to the introduction of gradient enhanced spectroscopy²⁰ in 1990 convinced us that the benefits of pulsed gradients in high-resolution NMR would eventually eclipse the drawbacks. The decision to develop shielded gradient technology for high-resolution NMR was also supported by concurrent studies, especially the work on diffusion-weighted water suppression by Van Zijl and Moonen²¹ and the demonstration of single shot heteronuclear coherence pathway selection by Knüttel et al.²²

Since 1990, application and development of NMR methods incorporating gradients has grown dramatically. High-resolution and in vivo NMR now benefit from all of the basic applications of gradients; the encoding of space, motion and coherence order, and the spoiling of unwanted magnetization.

R. Reid). Joined Nicolet Magnetics in 1980 (working with LeRoy Johnson on HR applications of NMR); 1983, manager CSI Applications, GE Medical Systems (formerly Nicolet Magnetics); 1989, manager Combined CSI and HR Applications; since 1990, manager Spectroscopy Research and Development. Approx. 60 publications, 4 patents. Current research: clinical MR spectroscopy.

Hyde, James S.: The NMR/EPR Interface at Varian, ENDOR, and notes on Zavoisky

James S. Hyde

Medical College of Wisconsin, Milwaukee, WI, USA

I was at Varian from 1959 to 1975. W. A. Anderson was my immediate supervisor, as he was for R. Ernst and R. Freeman. In turn, M. E. Packard was Anderson's superior. My assignment was to develop EPR, and these notes reflect on the interface between EPR and NMR at that time.

An early memory is of muted and serious discussions about whether or not the Bloch–Hansen patent¹ could withstand challenge because of the prior publication of the first EPR paper by Ye. K. Zavoisky. The Bloch–Hansen patent was filed on December 23, 1946. Zavoisky's dissertation was written in 1944, and the first paper appeared in 1945.² My understanding is that the challenge would be particularly serious if a copy of the Soviet journal could be found to exist anywhere in the US in 1946, but that none could be found.

I visited Zavoisky's colleague, S. A. Al'tshuler, in 1971 in Kazan. I can report that he told me that he and Zavoisky felt that they had seen an NMR signal in 1939 but that they were unable to make the resonance 'stand still'. He said that Zavoisky deliberately switched to electrons when he returned to research in 1942 or 1943 because of the larger moment. A sentence from the Al'tshuler and Kozyrev book³ catches some sense of their feeling for history:

'The discovery of an analogous effect in atomic nuclei, made by Purcell and Bloch et al. within two years after publication of Zavoisky's work, was a natural sequel to the study of paramagnetic resonance of electrons.'

I met Zavoisky at the meeting celebrating the 25th anniversary of the discovery of EPR held in Kazan in 1969. He delivered an interesting paper on ion cyclotron resonance in the gas phase. Somebody told me that he was involved in research on power generation using thermonuclear fusion.

I chose to try to advance the candidacy of Zavoisky for a Nobel Prize by speaking to a few key Swedish scientists. I came to understand that he had been seriously considered but that the failure to follow up the initial discovery by a sustained series of publications was considered detrimental.

Academician N. M. Emanuel kindly managed to supply a copy of Zavoisky's dissertation to Varian, and I recall looking it over. I know no Russian, but the equations, equipment drawings, and spectra were more or less familiar.

The debate on who was first in NMR no longer seems so important. A few years ago I challenged Martin Packard directly with the question, 'Is it true that you were the first person on the planet to see an NMR signal?' His reply was a mild, 'It's possible'. My question was based on the speculation that Packard, an experimentalist and Bloch's student, probably had the experiment working before showing it to his mentor.

In looking over other early Varian patents, I came across 3 068 399, 'Gyromagnetic Resonance Methods and Apparatus'.⁴ The first paragraph reads:

'This invention will be explained and described with reference to a nuclear resonance spectrometer system, but it should be understood that this invention is broadly applicable to atomic quantum systems in general, including those involving atom portions other than nuclei, for example, electrons.'

This is the spin-decoupling patent. As far as I know, no one has yet carried out an analogous EPR experiment.

My first EPR patent six years later⁵ was also entitled 'Gyromagnetic Resonance Methods and Apparatus', and starts out with a similar first paragraph. Efforts to write patents that are simultaneously applicable to NMR and EPR continue to this day.

The first true NMR experiment in which I was involved was electron nuclear double resonance (ENDOR) in liquids—detecting NMR signals indirectly by observation of EPR signals. G. Feher discovered ENDOR in 1956 when I was in the midst of graduate studies.⁶ A. H. Maki, who was a visitor at Varian in 1963, and I decided to see if ENDOR was possible for free radicals in the fluid phase. Earliest success occurred in a narrow window in time each day between 5 and 5.30 p.m. when for some reason our power lines were unusually quiet. I recall one very good week when the signal-to-noise ratio improved by a factor of 2 each day for five days in a row. Maki was in transit between Harvard and UC Riverside at the time. His parting words as I prepared to write up the first communication⁷ were, 'Make it sound important'.

Other early ENDOR experiments include ENDOR in unordered solids and on the ligands of copper complexes with G. Rist,⁸ and on a protein with L. E. G. Eriksson and A. Ehrenberg.⁹ Ehrenberg invited me to talk about ENDOR at the Second International Conference on Magnetic Resonance in Biological Systems held in Stockholm in 1966. At that exciting conference, W. D. Phillips reported the first NMR experiments on proteins, using the Varian 220 MHz superconducting magnet and spectrometer. H. E. Weaver, who had developed the first commercial EPR spectrometer in about 1956 based around the Varian wide-line NMR spectrometer, switched back to NMR to lead the development team for the spectrometer used by Phillips.

Richard Ernst, in his Nobel Prize address, acknowledged W. A. Anderson for the seminal role he played in these early days. I too would like to acknowledge his role and, in particular, the appendices of his dissertation paper.¹⁰ Here he describes magnetic field modulation in rigorous fashion in terms of double sums over modulation sidebands and intermodulation sidebands. In another appendix, the effect of two CW irradiating radiofrequency fields is discussed. Thirty-five years later, these two appendices served as the basis for experiments on multiquantum EPR.¹¹

We recently reported liquid phase ENDOR by detection of the effect of inducing an NMR transition on an EPR intermodulation sideband that is produced when two equally intense microwave frequencies that lie within a homogeneous line irradiate an EPR transition.¹² I suggest that this fairly elaborate spin physics had its origins in the heady environment of the early NMR days at Varian.

Jackman, Lloyd M.: NMR in Organic Chemistry—the Fabulous Fifties

Lloyd M. Jackman

The Pennsylvania State University, University Park, PA, USA

‘Have we ever thought of writing a book?’, asked Professor Derek Barton, who had just walked into my office in Imperial College. I recognized the editorial ‘we’, and with what was perhaps excessive enthusiasm told him that indeed I was just beginning one on the mechanisms of oxidation and reduction reactions.

‘Ah, an important subject’, he replied. ‘But one only writes a book to make one’s fame or fortune and a book on oxidation will do neither. Why don’t we write one on NMR spectroscopy?’

And so it was that I came to chronicle the explosion of NMR spectroscopy into the field of organic chemistry that occurred in the 1950s.

Most of us had already adopted IR and UV/visible spectroscopy for functional group analysis and were therefore immediately receptive to this new technique. For some, however, it created difficulties. For example, one eminent chemist on reviewing a structure I had derived from its NMR spectrum pronounced it ‘interesting’ but added that he thought they would ‘do a little chemistry’. I suspect that he really accepted my structure but wistfully realized that the beautiful structure proofs based on series of chemical degradations that had constituted the high arts of organic chemistry were about to leave the stage.

Organic chemists were dazzled by the early spectrometers with their massive electromagnets and huge power supplies. My first views were provided by color slides of a Varian HR-40 (yes! 40 MHz) presented in a lecture by Prof. Jack Roberts who later provided me with my first NMR spectrum. Subsequently, Prof. Wilkinson purchased this instrument for the Inorganic Chemistry Department at Imperial College and kindly allowed me access to it. It was installed for us by Dr. Warren Proctor, one of the pioneers in the field. By locating the probe just outside the pole faces of the magnet he picked up a signal from a sample of diphenylpicrylhydrazyl and pointed out that we had also purchased an ESR spectrometer. Finally, he gave us a lecture on spin Hamiltonians.

These early spectrometers were quite outside the experience of organic chemists. Shimming was accomplished by a mysterious mixture of cycling the magnet current and mechanically distorting the magnet itself. Field/frequency locks had not been commercially developed and so precalibrated spectral charts could not be used. Calibration was accomplished by introducing audiofrequency sidebands into spectra and the frequency separations of signals were obtained by averaging data from several spectra. Integration was generally performed by ‘cutting and weighing’ the peaks in the spectra.

The application of NMR in organic chemistry depends mainly on two phenomena, the chemical shift and spin–spin coupling. The pioneering work of Gutowsky and others at the beginning of the decade thus set the stage for the entry

of NMR into organic chemistry. In particular, a 1953 paper of the Gutowsky group in which they listed 150–200 proton chemical shifts for protons in various chemical environments clearly demonstrated the enormous potential of NMR. Shortly thereafter two valuable compilations of proton chemical shifts made by Drs. N. F. Chamberlain and G. D. V. Tiers became available to many in the NMR community and these contributed greatly to the development of the subject. Unfortunately, during this period much confusion reigned regarding both the method of referencing spectra and the definition of the proton chemical shift scale. Bothner-By and Glick pointed out the fallacy of using an external reference contained in a coaxial capillary tube and it was left to George Tiers to suggest the ideal internal reference, namely tetramethylsilane. Even then, there was controversy whether the ppm scale should increase or decrease with increasing shielding. Eventually the latter was adopted to be consistent with the scales used for other nuclides.

During the latter part of the decade, NMR spectroscopists were devoting much attention to the analysis of the spectra of complex spin systems. Since access to computational methods was somewhat limited, clever techniques, such as subspectral analysis, which avoided quantum mechanical calculations, were developed. The utility of spin decoupling experiments was recognized but the commercial spectrometers did not yet offer the capability of double irradiation. During this period, many organic chemists became comfortable with unraveling first-order spectra although ‘virtual coupling’ and ‘deceptively simple spectra’ caused some confusion.

The 1950s was also a period of intense interest in conformational analysis. The appearance of the ‘Karplus equation’ relating the magnitude of the vicinal coupling constant to the dihedral angle was therefore greeted with great enthusiasm. Here was a powerful, new method for establishing conformation and relative stereochemistry, particularly in alicyclic systems.

By the end of the decade, proton NMR spectra of representatives of most of the major groups of natural products had appeared in the literature and NMR spectroscopy had contributed significantly to proofs of the structure and/or the stereochemistry of carotenoids, alkaloids, terpenoid substances, plant phenolics, mold metabolites, and carbohydrates. It is hard to convey the exhilaration which many of us felt when we succeeded in establishing a structure that we knew would have taken a lengthy series of experiments to achieve or that, for reasons of sample limitation, could not easily be tackled by chemical methods. Just as exciting was to see organic chemists come to recognize that NMR trivialized many simple problems and that it could be employed to monitor many reactions used in synthetic organic chemistry.

The decade closed with the appearance of the Varian A-60 spectrometer, which operated with a field/frequency lock and could therefore record spectra on precalibrated chart paper. NMR was now a ‘hands-on’ tool for the bench organic chemist. Its impact was immediate and enormous.

Perhaps some of us felt the excitement was over. We knew that 100 MHz spectrometers were coming but we could not envision 750 MHz. We believed that one day routine ^{13}C NMR might somehow be possible, but our crystal ball certainly did not reveal FT NMR and the multiplicity of $(1+n)\text{D}$ techniques it has brought with it. We knew of the nuclear Overhauser enhancement but few, if any, recognized that it would take

its place alongside the chemical shift and spin–spin coupling constant as a key parameter for the elucidation of structure and stereochemistry. And imaging. Impossible!

of Science and Technology, University of London (with Sir Patrick Linstead and E. A. Braude). Successively lecturer, senior lecturer, and reader at Imperial College, Professor of Organic Chemistry at University of Melbourne, Professor of Chemistry at The Pennsylvania State University. Currently Professor Emeritus at Penn. State. Approx. 160 publications including book ‘Applications on Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry’. Current research specialty: structures, reaction mechanisms, and NMR spectroscopy of organic lithium compounds.

Jakobsen, Hans J.: A Retrospect on the Development of High-Speed Sample Spinners for Solids since 1980

Hans J. Jakobsen

University of Aarhus, Aarhus, Denmark

Although the method of magic angle spinning (MAS) for obtaining high-resolution NMR spectra of solids was established long before 1980, it was at that time still considered a technique for the specialists. One reason for the long-awaited breakthrough of the methodology was the commercial inaccessibility of stable and routinely spinning MAS probes. The painful struggle to obtain decent spinning by carefully packing/repacking rotors undoubtedly prevented many newcomers from entering the field at that time. Before 1980, the most widely used spinner designs were those after Andrew¹ employing a conical surface with a single air-bearing and drive source. However, cylindrical rotors with separate bearing and drive systems also emerged at that time (e.g. by Lippmaa et al and by Veeman et al.).² Around 1980 the maximum attainable spinning frequency was generally considered to be $\nu_r = 4\text{--}5$ kHz.

During 1978–83, our laboratory was heavily engaged in collaborative research projects with Paul D. Ellis, University of South Carolina (USC). Following a sabbatical in John Waugh's lab (1976–77), Paul was very excited about setting up instrumentation for solid state NMR at USC. I became infected by Paul's enthusiasm and decided to introduce high-resolution solid state NMR in Denmark when purchasing our new spectrometer.

One of Paul's graduate students engaged in designing the USC solid state NMR equipment was David Doty. During a visit to USC in December 1979, I witnessed Dave working hard on having a prototype MAS spinner operating before Christmas. At a students' Christmas party at Paul's house, Dave and his wife Judy were the last to arrive. When entering the room Dave and Judy were each blowing an air hose and the rotor was actually spinning in Dave's first cylindrical spinner assembly. Improvements of the design resulted in an 8-mm spinner assembly with a maximum $\nu_r \approx 5$ kHz and the Doty and Ellis review² of their design. The successful development of NMR equipment at USC during these years undoubtedly convinced Dave to found his own company, Doty Scientific, Inc., in 1982 (see *A Random Walk Toward High-Speed Sample Spinning*) and Doty 5-kHz MAS probes were soon on the market.

Following the installation of a Varian XL-300 liquids/solids spectrometer at University of Aarhus (UAa) in 1983, a decision was made one year later to improve the spinning performance of the original Varian pneumatic MAS probe by designing our own spinner assembly. The objective was routinely to spin inhomogeneously packed samples in a 7-mm cylindrical rotor at 5–6 kHz. The basic idea was a stiff air-bearing

system, an experience gained from USC,² however using an otherwise new design. Following a year of 'ups and downs' in design/construction, we (Vagn Langer, Preben Dagaard, and myself) finally recorded our first 5-kHz MAS spectra in early 1985. A period of competition for pushing the limit of 'high-speed spinning' started right away. By early 1986 our spinner assembly was considerably improved and we routinely recorded 10-kHz MAS spectra using 7-mm rotors.³ A collaboration on high-speed MAS probes was initiated with Varian Associates following the patent of our design.

At the 8th European ENC, Spa, Belgium in June 1986, our spinner system was presented live to the scientific community. Furthermore, at that conference, Doty Scientific for the first time presented its products in Europe. Considering the efforts in starting up a new company, Dave had carried out few improvements in high-speed spinning since he left USC. Watching our 7-mm rotor perform at $\nu_r = 10$ kHz, Dave got excited and said quietly, 'I need to go back to the workshop'. Some months later Dave phoned us back, 'I have 10 kHz for my 7-mm rotor'.

During the same time period, developments of high-speed spinner systems were being performed at the University of Colorado by Dec, Wind, and Maciel. In 1986 this group published MAS spectra for 4.5-mm o.d. rotors spinning at 17 kHz using air.⁴ Thus the competition on high-speed spinning kept going.

It did not take long for the UAa lab to modify our spinner assembly for 5-mm o.d. rotors⁵ (maximum $\nu_r = 16.4$ kHz) which was presented at the 28th ENC, 1987. This was followed by the introduction of a 4-mm o.d. rotor system with a maximum $\nu_r = 20.6$ kHz at the 31st ENC, 1990. Comparable improvements were achieved by Doty Scientific during these years.

The maximum attainable ν_r values for our various rotor sizes are determined by the largest outer diameter of the rotor/end-cap system, for which a speed equal to the speed of sound (346 m s^{-1} at 25°C) can be observed in all cases. For our rotor design, the diameters for the end-caps are all larger than the rotor o.d., e.g. 9.80, 6.75, and 5.00 mm for the 7, 5, and 4 mm rotors. These rotors yield maximum ν_r values of 11.4, 16.4, and 20.6 kHz, corresponding to speeds of 353, 348, and 324 m s^{-1} for the end-cap o.d.s, i.e. about the speed of sound but not above.

During recent years the possibility of supersonic MAS has been investigated both at Doty Scientific and in our lab. For example, $\nu_r = 26$ kHz has been observed for a 3.5-mm rotor at Doty Scientific. At UAa we have increased the rotor speeds by (i) reducing the largest o.d. for the end-cap and (ii) modifying the drive jets. For example, for the 7-mm rotor with an 8.2-mm o.d. end-cap and new drive design, we have observed $\nu_r = 14.5$ kHz corresponding to a speed for the largest diameter of 374 m s^{-1} , i.e. supersonic above 13.5 kHz. Provided our future efforts further to reduce the end-cap o.d.s to that of the rotors are equally successful, we should obtain spin rates of 17, 24, 30, and 34 kHz for 7, 5, 4, and 3.5 mm rotors, respectively. An exciting prospect for the future of MAS NMR.

James, Thomas L.: Time for Preparation and Evolution. But what is the Mechanism for Relaxation?

Thomas L. James

University of California, San Francisco, CA, USA

I first learned of the potential application of NMR to problems of biochemical interest while in my first year (1965–66) of graduate school in the Biochemistry Department at the University of Wisconsin, Madison, where I had matriculated following graduation from the University of New Mexico. Loren Anderson, the instructor in the introductory biochemistry class, was properly excited by the then-unpublished studies of R. U. Lemieux and J. D. Stevens on sugar conformations. While I retained an underlying interest in biochemical processes, at that time my limited perception was that biochemistry as a discipline was too empirical. So I switched to the Chemistry Department at Wisconsin in that first year and began graduate research looking at protonation via NMR in the lab of Asst. Prof. Richard J. Kula, who had recently obtained his Ph.D. from the University of California, Riverside, in the labs of Donald Sawyer and Sunney Chan. In my second year of graduate school, Rich announced he was returning to California, specifically the greener hills of Berkeley and the greener pastures promised by the study of law. As I had also acquired an NIH predoctoral fellowship providing a small amount of research money in addition to my salary by then, I had an unusual situation for a graduate student: I had nearly complete freedom to devise a thesis project on my own, a little experience, and a strong interest in a field only in its infancy—biological NMR. By that time, I had read the few pioneering papers by Mildred Cohn, Oleg Jardetzky, William Phillips, and Robert Shulman, and found those relating NMR relaxation to biochemical problems to be particularly interesting. With so little prior literature, I simply leafed through my biochemistry textbook, picked four subjects I thought appropriate for study via NMR relaxation, and worked out a plan for one: use of ^{23}Na NMR relaxation to examine aspects of the active transport of sodium across biological membranes. With this plan, I approached Joe Noggle whom I was told was acquiring a pulsed NMR spectrometer. Joe accepted me into his lab and enthusiastically encouraged me to pursue the project. As there was little prior work with ^{23}Na NMR studies of complexes, I carried out some studies of other sodium ion complexes, but eventually was able to study the interactions of sodium ion with the Na–K transport ATPase, which purportedly was involved in membrane transport.

After a two-year hiatus in the chemical industry in Texas studying aspects of heterogeneous catalysis without a single NMR experiment, I longed for the challenge of NMR, biochemistry, and academe. I was able to join Mildred Cohn's lab in the Johnson Research Foundation (Biophysics) at the University of Pennsylvania, where mostly I used NMR to study aspects of enzymology. I also found time on the side in my first year there to do some self-diffusion studies in biological

tissue. Mildred taught those in her lab to focus on the scientific question, not on the technique, i.e. NMR. I have tried to adhere to this focus with modest success ever since. (I have learned that this view is strongly shared by most NIH study sections as well.)

At the time of my postdoctoral work, i.e., early 1970s, many others were starting work in biological NMR or were interested. Several people asked me where they could learn sufficient NMR to conduct biochemical studies. Physics books on NMR were considered too daunting, and chemistry books typically skirted relaxation which was so important for biochemical and biological applications. Consequently, I wrote the book 'NMR in Biochemistry' at nights and weekends during the second year of my postdoc. However, I had acquired a faculty position in the Pharmaceutical Chemistry Department at the University of California, San Francisco, before the book was in print.

In my latter months at Penn, I used intermolecular NOE experiments to examine the interaction of a ligand with specific amino acyl residues at an enzyme active site. After a frustrating first year at UCSF without access to a decent NMR instrument, I continued with further NOE studies on the high-field spectrometer at Stanford. We were subsequently successful in funding our first research-grade instrument at UCSF. Not long after, the emphasis of my research shifted to DNA with a lower level of activity remaining with proteins. Relaxation remained a major interest with studies of molecular motion later being displaced by structural studies centered around measurements of internuclear distances via complete relaxation matrix analysis of 2D NOE spectral intensities.

Although studies of sickle cell disease with erythrocytes in NMR tubes were initiated with Irwin D. (Tack) Kuntz soon after my arrival in San Francisco, developments in magnetic resonance imaging by colleagues at UCSF and in vivo NMR in general elsewhere brought numerous local colleagues to my door to inquire how NMR might be useful for their research interests. Three such inquiries on one particular day convinced me that I should either get seriously involved with in vivo NMR or change my phone number—I chose the former. Consequently, I became involved in several projects with local collaborators utilizing systems ranging from cell cultures to perfused organs, to animals, and to humans.

My research has profited immensely from the intellectual milieu of UCSF; in particular, the molecular studies have benefited from long-term interactions with Vladimir J. Basus, Peter A. Kollman, Tack Kuntz, and Richard H. Shafer, and the in vivo NMR studies have benefited from a long term interaction with Lawrence Litt. I have also had the privilege of having several talented postdocs and graduate students in my lab, most of whom have now left to pursue successful careers elsewhere.

Jameson, Cynthia J.: Early Work on the Ranges of Chemical Shifts and Signs of Coupling Constants

Cynthia J. Jameson

University of Illinois at Chicago, Chicago, IL, USA

When I came to the University of Illinois at Urbana-Champaign as a graduate student, Herb Gutowsky's group had the only computer program in existence for the computation of high-resolution NMR spectra of a general six-spin system. It was written by Geneva Belford and ran on that marvelous machine (for its time) the Illiac I. I was using it to compute the proton spectrum of the $-\text{CH}_2\text{CH}_2-$ groups in [2.2] metacyclopentane (in which the methylene groups are locked in virtually symmetrical staggered positions, with tetrahedral bond angles), an AA'BB' spectrum which at 60 Mc s⁻¹ looked almost of the A₂X₂ type. The quality of the spectra, calibrated by the usual audiofrequency sideband method, was such that even at this high field I could distinguish between sets of chemical shift and coupling constant parameters by focusing on the relative intensities and splittings between two sets of small peaks. I came to the conclusion that it was impossible to fit the spectrum using uniformly positive coupling constants. Jim Shoolery at Varian Associates kindly ran a low-field spectrum for us (15.083 Mc s⁻¹) and this was definitely AA'BB'. There was excellent agreement with the assignment $J_{\text{trans}} = +12.3$, $J_{\text{gem}} = -12.0$, $J_{\text{gauche}} = +4.0$, and $J_{\text{gauche}}' = +3.2$ Hz and, of course, with the other set in which all the signs are reversed. The key finding was that J_{trans} and J_{gem} , the two largest coupling constants were opposite in sign.¹

I was convinced that I had logically exhausted all the possible combinations of the parameters to test against the spectra, but Herb did not have confidence in my results at that time. After all, Martin Karplus (with Anderson, Farrar, and Gutowsky) had calculated these coupling constants in CH₄ and the H-C-C-H fragment in two classic papers,^{2,3} the latter being the original paper about what was to become known as the Karplus relationship. Both papers were considered to be in good agreement with experiment, and in CH₄ itself the calculated magnitude of the coupling constant was right on. My results went into a hole for several months until Herb (with Dave Grant) started looking into the nature and analysis of A₂B₂ and A₂X₂ spectra in general, and became convinced that I was right after all. The implications of this finding were unfortunate, or so we said then, for it meant that one of the two calculations was in error. It turned out that it would be decades later before the J_{gem} value could be calculated properly, but the H-C-C-H fragment calculation lives on.

The synthesis of the xenon fluorides generated a lot of excitement during this time and there was a great deal of speculation about the nature of the bonding in these molecules. Tom Brown told Herb about the ¹²⁹Xe chemical shifts that he and Whipple obtained indirectly by INDOR on the ¹⁹F well before the paper came out in *Science*.⁴ The shifts were very large, Xe was deshielded by 5785 ppm in XeF₄ compared

to the Xe in xenon gas, for example, and among the three fluorides XeF₂, XeF₄, and XeOF₄ the spread was very nearly 2000 ppm. Were the shifts as large as they were because the bonding in these new compounds was highly unusual, i.e. drastically different from ordinary compounds? Herb asked me to 'explain' the very large Xe chemical shifts. I figured that I could not 'explain' the large magnitudes of the chemical shifts of Xe in these compounds in isolation. It would only be a credible explanation if at the same time I could explain why some nuclei have large chemical shifts while others were much smaller in the regular compounds for which the nature of the bonding was not in question. After collecting the entire chemical shift data known at that time (a mere handful of nuclei) and putting the ranges of their chemical shifts in the Periodic Table, I thought I could see a Z-dependence that might possibly be periodic. I look back on the very fragmentary information on which I based this leap of faith and think that it's amazing how graduate students have no fear. What could be causing this periodic behavior? If I could find a logical reason for the chemical shifts to behave that way then there is no problem with Xe, for I could almost see the rising trend in going from left to right in a row of the Periodic Table and within a group, from top to bottom, so that Xe would logically be at a peak in the row and also in the column of rare gas nuclei.

Well, I did not find the answer immediately. I got married and left to join my husband out east. While browsing around in the library in Columbia University, looking at the paper on chemical shifts of xenon in the gas phase at high pressures by Carr and the explanation of the relaxation of ¹²⁹Xe in xenon gas by Torrey, I happened upon the paper by Barnes and Smith in the same volume of the *Physical Review* (with computerized information retrieval this would never have happened). This paper was entitled 'Electric Field Gradients of Atomic p Electrons'.⁵ Off-hand one would not think that this had anything to do with chemical shifts, but I was just browsing. So I read about the determination of the spin-orbit coupling constants for the atoms from the term energies and the calculations of the average value of $1/r^3$ for the p electron from these constants. And there it was, the periodicity that I was looking for. The $1/r^3$ term that appears in the operator for the paramagnetic part of the nuclear magnetic shielding in Ramsey's formulation has an average value for the free atoms that was periodic in the way that I imagined the ranges of chemical shifts were periodic. It did not take long after I made this serendipitous discovery to write it up and send it off to Herb, and we polished it up during a two-week visit I made to Urbana.⁶ Of course, now that most nuclei in the Periodic Table have been observed extensively, the ranges of the chemical shifts of the nuclei show the periodic behavior very beautifully, tracking the periodic behavior in the average values of $1/r^3$ for the atoms.⁷

Jardetzky, Oleg: NMR in Molecular Biology—A History of Basic Ideas

Oleg Jardetzky

Stanford University, Stanford, CA, USA

Attempts to apply NMR to biology did not lag far behind the first applications in chemistry. Even in 1954, Jacobson, Anderson, and Arnold¹ had tried to measure the hydration of DNA via the intensity of the NMR water signal in DNA solutions. The reported observation was later shown to have been an instrument artifact, but a beginning had been made.

My own involvement with NMR began at about the same time. As a graduate student interested in Na^+ transport across biological membranes and discouraged by the fashion of treating the membrane as a black box, I was looking for a new approach to the problem. One of my advisors, the chemist Bill Lipscomb, suggested NMR as a possibility. The other, the physiologist Maurice Visscher, said wisely: ‘the unexplored is always tempting—see what you can do’. An Na^+ resonance had not been seen before, but John Wertz raised the funds to construct a 7.9 MHz oscillator for Na^+ at 7 kG. Hence my thesis became the first NMR study of the interactions of Na^+ ions in solution and the first published detection of an NMR signal in living matter. We did not learn much about transport, but something about complexing of Na^+ with intracellular proteins and a variety of metabolites (Figure 1).²

The inspiration for a systematic investigation of the potential of NMR in molecular biology came from the first comprehensive review of the NMR literature by John Wertz in 1955.³ Wertz likened the resonating nuclei to the radio transmitters of spies reporting what the surrounding atoms were doing. At the time, the Watson–Crick DNA double helix was barely two years old and, for lack of conclusive evidence, by no means universally accepted. Protein crystallography was at a hopeful rumor stage. The prospect of studying biological macromolecules at atomic resolution was tantalizing.

We began our systematic study of protein and nucleic acid building blocks—amino acids, small peptides, then mono- and oligonucleotides—in 1956.⁴ When the first NMR spectrum of a protein (ribonuclease) was recorded by Saunders, Wishnia, and Kirkwood in 1957,⁵ we were in the position to account for its general shape from the spectra of constituent amino acids.⁶ The initial result was disappointing. Instead of detailed reports, only messages scrambled by overlap-jammed airwaves. One observation of lasting value did emerge from a few additional experiments: mobile regions in biopolymers could be distinguished from the compact structure by their narrow lines. This prompted us to develop a relaxation method for the study of molecular interactions.⁷ Among our first findings was that the aromatic substituent on penicillin, rather than the penicillanic acid moiety, was responsible for its binding to serum albumin. The method still finds some use today and was recently reinvented, without reference to the original work.⁸ Estimates of expected widths for amino acid lines (of known chemical shift) in ‘rigid’ proteins led as early as 1961 to the conclusion that the observed broad envelopes

Figure 1 ^{23}Na resonance in blood and blood fractions. (Taken from Jardetzky, *Ph.D. Thesis*, 1956²)

were due only in part to the high molecular weight, but in part also to chemical shift nonequivalence.⁹ This meant hope.

The classes of problems in molecular biology that NMR could solve were clear from prototype experiments by the time we wrote our first review on the subject in 1961: ‘(a) *primary structure*, (b) *conformation* or *secondary* and *tertiary structure*, (c) *rate processes* and *molecular motion* and (d) *interactions* between molecules’.⁹ The agenda has remained the same since, but specific information within it has grown explosively over 30 years.

The major obstacles standing in the way of detailed structural studies on proteins and nucleic acids by NMR were rapidly recognized as those of *sensitivity*, *resolution*, and *rules of interpretation*.

The problem of *sensitivity* was solved first. In 1962, inspired by radioastronomers, we instituted signal averaging, for the first time attaching a small computer (CAT, computer of average transients) to the NMR spectrometer. This achieved a roughly 100-fold improvement in signal-to-noise ratio.¹⁰ In 1963, similar experiments were reported by Klein, Allen, and Laszlo, but it still took nearly two years before the CAT became part of a commercial spectrometer. The menagerie of averaging methods grew rapidly, including the DOG (very slow sweep) and the MOUSE (a simple capacitor circuit). However, CAT NMR became the standard method of the 1960s. This was ironic, because the better—now universally used—solution had been conceived almost simultaneously. Discussing our initial results at a 1962 Gordon Conference (more precisely, swimming in Webster lake), Richard Ernst suggested that it may be more efficient to average in the time rather than in the frequency domain. This idea became the basis of modern Fourier transform (FT) spectroscopy. It took four years to bring to fruition¹¹ and it was 1970 before FT spectrometers became generally available. A variety of technical advances has improved sensitivity by an additional factor of 20–30 since the introduction of signal averaging, yet the practical gain in macromolecular spectroscopy has been much less. It was then possible to look at millimolar solutions of proteins—and it is now still necessary to look at millimolar solutions. The relative ‘loss’ of sensitivity is, of course, due to the fact that in the 1960s one was looking at the main spectral

lines, while at present one is deriving information from the much less intense cross peaks in multidimensional spectra.

The problem of *resolution* in macromolecular spectra can at present be regarded as essentially solved by the development of three technologies: (1) high-field magnets, allowing frequencies above 500 and now up to 750 MHz; (2) 2D and later multidimensional FT spectroscopy; and (3) isotopic spectral editing. Now the spectra of small proteins and oligonucleotides ($MW < 10$ kD) can often be assigned by spectroscopic experiments alone. However, at higher molecular weights simplification of spectra by isotopic labeling has proved indispensable. The solution emerged in stages over a 20-year period and in reverse of the order listed.

The highest frequency spectrometer available in the mid-1960s—based on the first Varian superconducting magnet designed by Harry Weaver—operated at 220 MHz. In the hands of W. D. Phillips and his colleagues at DuPont it gave promising, but not sufficient, improvements in the resolution of protein spectra.¹² Based on our knowledge of chemical shift differences observed in peptides and the amino acid composition of several proteins, it was possible to estimate that even at fields of 1000 MHz a complete resolution of the proton NMR spectra of proteins of moderate size (MW 17–20 kD) could not be expected. At the historic NMR meeting in Tokyo, organized in 1965 by Shizuo Fujiwara, himself a pioneer of amino acid and peptide NMR, I therefore proposed that to extract detailed information on individual residues it would be necessary to simplify protein NMR spectra by selective deuteration.¹³ We made a detailed list of desirable criteria for the protein to be studied—a single chain, moderate molecular weight, bacterial origin, ease of preparation, knowledge of the primary sequence, etc.—and through a serendipitous encounter with Chris Anfinsen, who had recently isolated and sequenced staphylococcal nuclease, we found an ideal system.

The proposal was implemented by 1968 by Markley, Putter, and Jardetzky¹⁴ with a dramatic and informative simplification of the nuclease spectrum (Figure 2) and by Crespi, Rosenberg, and Katz for phycocyanin,¹⁵ for which, however, no structural studies were reported. In the case of staphylococcal nuclease, spectral editing allowed the first detailed NMR study of the structure and dynamics of an enzyme–inhibitor complex.¹⁶ The use of ^{13}C for spectral editing was proposed in 1970 by Paul Lauterbur and the use of ^{15}N in 1976 by Aviva Lapidot. Spectral editing was used sporadically through the years for assignment and simplification, but did not really come into its own until the late 1980s when it became generally recognized that even multidimensional proton spectroscopy would not allow a complete spectral assignment for larger proteins. Since that time many ingenious labeling schemes described elsewhere in this work have been invented and have become an indispensable component of protein structure determination by NMR. To tackle the largest structures thus far solved by NMR—the *trp* repressor (25 kD) and its DNA complex (37 kD)—we had to use a combination of heteronuclear 3D and selective deuteration.¹⁷ It can be expected that this combination will be essential for the NMR study of larger structures in general.

The most dramatic of the three methodological contributions to the solution of the resolution problem for macromolecular spectra has been first two-dimensional and later multidimensional FT spectroscopy. Following up on the initial suggestion

Figure 2 Comparison of the aromatic region of the NMR spectra of (a) staphylococcal nuclease and (b) a selectively deuterated analog. Assignments: His, H1, H2a, H2b, H3 and H4 (the low-field peaks are C-2 and the high-field peaks C-4 imidazole protons); Tyr, Y1-7 (2,6-protons); Trp, W (C-2 ring proton). (Taken from Putter et al., 1969¹⁴)

by Jean Jeener in 1971, the development of the theory of the method and of many key experimental techniques has for the most part been the monumental contribution of Richard Ernst and his school, summarized in their 1987 book¹⁸ and elsewhere in this volume. Applications to proteins emerged rapidly in several laboratories—particularly at Oxford, Stanford, and Zurich.¹⁹ As long as attention was focused on very small proteins, it appeared that nothing else was needed to solve all problems of protein NMR spectroscopy. The fact that we now know this not to be true in no way detracts from the enormous value of multidimensional spectroscopy, even if its success depends on high-frequency spectrometers and its most important contributions are bound to be in its isotope edited form.

The development of high field magnets played a decisive role in the development of protein and nucleic acid NMR. Instrumental resolution has improved by a factor of 15–20, compared to the 40 MHz ribonuclease spectrum in 1957. The contributions of many individuals lie behind this development and these are described elsewhere in this volume. Landmarks of progress were the 270 MHz instrument at Oxford in 1971, the 360 MHz at Stanford in 1974, the 600 MHz at Pittsburgh in 1979, and the 750 MHz at Oxford in 1992.

The *interpretation* of NMR findings on macromolecules must still be regarded as an incompletely solved problem, even though some of the fundamentals are well understood. The basic question: What kind of information about protein structure does an NMR spectrum contain?, had not been answered by the early finding of chemical shift dispersion among chemically identical residues in the spectra of native proteins. Was this dispersion due to primary structure effects of nearest neighbors? To secondary structure? To tertiary folding? A series of investigations on model systems and on protein denaturation, largely in our laboratory and that of W. D. Phillips, answered these questions by 1967. It was shown that in linear peptides and random coil polymers, primary sequence effects were small. The 1964 proposal by M. Sheinblatt to use NMR for the sequencing of proteins

proved applicable only to very short peptides, where titration shifts of the N- and C-terminal residues could be detected. Markley, Meadows, and Jardetzky²⁰ first demonstrated that the formation of α -helices was accompanied by a + 0.4 ppm shift of the α -CH resonances. This and other regularities in peptide spectra were summarized by Nakamura and Jardetzky.²¹ Crucial were the denaturation experiments of Cohen and Jardetzky²² and McDonald and Phillips²³ which showed that the spectrum of a denatured protein was, to a good first approximation, the sum of the spectra of the constituent amino acids. In particular, our study of lysozyme denaturation revealed differences between the native, partially denatured (still disulfide-linked) and fully denatured (reduced) forms of the enzyme. The partially denatured form—now called the molten globule—has become a favorite object in studies of protein folding. Denaturation studies on selectively deuterated staphylococcal nuclease provided additional decisive evidence.¹⁶ It was thus clearly established that the protein NMR spectrum contained information on the secondary and tertiary structure of the native protein.

From the beginning, an important task was to identify specific questions that NMR could answer in protein chemistry and to design prototype experiments to demonstrate feasibility. Spectroscopists often tend to forget that only a small fraction of the techniques they invent are relevant to the study of macromolecules—and that the selection process is not straightforward. The technique must be matched to the biological question. Most important for protein function was a description of conformational transitions and of the behavior of ligands at active sites—neither easily studied by crystallography. At the relatively low spectrometer resolution and high cost of isotopic spectral editing, a complete structural analysis of a protein by NMR remained beyond reach in the 1960s and 1970s. Our own efforts therefore centered on the study of partial structures—the structures of drug and enzyme inhibitor complexes. Relaxation measurements were used to define the geometry of small molecular weight ligands such as penicillin,²⁴ the sulfonamides,²⁵ or acetylcholine derivatives²⁶ in a protein binding site. More complete structures of the complexes of nucleotide inhibitors with pancreatic ribonuclease²⁷ and staphylococcal nuclease¹⁶ could be deduced from the patterns of chemical shift changes in both the ligand and in protein side chains. A reliable geometry could be obtained only with prior knowledge of the crystal structure of the free protein. Nevertheless, the structures deduced were shown to be correct by subsequent crystallographic and structural NMR studies. In the case of ribonuclease they provided us with a solid structural basis for proposing a detailed mechanism of enzyme action²⁸ which predicted subsequent kinetic results²⁹ and stood the test of time.

The importance of relaxation parameters for defining the geometry of macromolecules and their complexes was clearly understood as early as 1964. In my article in the *Advances in Chemical Physics*⁷ it was pointed out that in contrast to chemical shifts and coupling constants, relaxation parameters ranked as ‘the potentially most informative measurements’, that cross relaxation between two protons could be measured, and the internuclear distances could be used to define geometry. This is now standard practice, but the degree to which it was considered unrealistic even six years later can best be conveyed by citing verbatim an exchange which took place at the Ciba Foundation Symposium in London in 1970

during the discussion of my paper on the structure of the nucleotide–staphylococcal nuclease complex:³⁰

F. M. Richards: Without reference to other techniques, how much information could you specify ... ? Are you able to specify distances and orientations to the other groups whose signals you can measure, or put certain limits on them?

O. Jardetzky: ... In principle you can get this information if you measure relaxation times and the dependence of relaxation times on each neighbor in the vicinity.

H. M. McConnell: That is an exaggeration!

O. Jardetzky: It is (only) an exaggeration in the sense that it is a diabolically difficult undertaking. It is a very hard thing to do, but if you did have just two protons, you could make a good guess about the distance between them. Admittedly nobody has tried to do this.

Everyone was doing it 20 years later.

To acknowledge reality, the 1964 article⁷ not only summarized the principles of obtaining structural information but also defined the difficulties of interpreting NMR parameters measured on macromolecules. These difficulties are still with us. The relaxation equations proposed then for the study of proteins and protein complexes for the first time included individual spectral density functions for each internuclear vector, and internuclear distances averaged over time, to take into account internal mobility and the resulting averaging of geometric parameters. The formulation made it clear that interpretation of relaxation measurements on molecules with many degrees of internal motional freedom is a severely underdetermined problem. Calculating distances from relaxation parameters—be they T_1 , T_2 , or NOE—is treacherous, because each parameter is a function of *both* an unknown distance and an unknown time function. Averaging brings with it additional uncertainties, and we pointed these out in 1980.³¹

Discoveries of internal motion, evident not only in relaxation parameters but also in the averaging of chemical shifts, began accumulating rapidly. The free rotation of tyrosine rings in the interior of globular proteins was first discovered in the isotope edited spectra of staphylococcal nuclease in 1968. The phenomenon was carefully studied by Campbell, Dobson, and co-workers in 1975³² and subsequently by many others. In 1974 we were able to draw a distinction between librations and ‘ring flipping’ by comparing ^{13}C relaxation measurements and chemical shift averaging in parvalbumin, leading us to point out that placing a cage of six relatively rigid α -helices onto a quivering hydrophobic core conveyed conformational flexibility to an otherwise rigid molecule.³³ In the late 1970s we also demonstrated flexibility in the RNA-binding region of tobacco mosaic virus, the DNA binding region of the *lac*-repressor, and in myosin.³⁴ Similar observations were soon made on the pyruvate dehydrogenase multienzyme complex.³⁵ The general importance of dynamics, especially in nucleic acid binding regions, has only recently become apparent, as numerous additional examples began appearing in the literature.

Structural work on small proteins in the 1980s largely ignored dynamics, treating proteins and oligonucleotides as rigid spheres. The success of this first approximation for defining the protein fold has been remarkable, but the inaccuracy introduced remains undetermined. For more complex proteins, problems of structure and dynamics have to be solved simultaneously. To determine an NMR structure, we have to understand its dynamics—and to understand the

dynamics we must know the structure. This clearly requires information from methods other than NMR.

Nonetheless, efforts to obtain complete 3D structures began in the early 1970s. The 'lanthanide method' advanced by R. J. P. Williams and his colleagues³⁶ attracted considerable attention as it promised to provide all the distance and angular information needed for a complete protein structure determination by measuring the paramagnetic shifts and relaxation effects of lanthanide ions bound at specific sites on the protein. The method provided some useful information on the structure of calcium-binding proteins, but generally failed because of the prevalence of nonspecific ion binding sites and for theoretical reasons discussed by us in 1981.¹

Deriving information from unperturbed protein spectra appeared more promising generally. A significant conceptual advance was the paradigm developed by W. Gibbons in 1975, combining coupling constant and NOE measurements to obtain a sequential assignment of resonances in a peptide.³⁷ The assignment of an NH and α -CH (and other groups) within the same residue was made from CH-CH and CH-NH coupling constants, and the proximity between NH (i) and NH ($i + 1$) as well as CH ($i + 1$) was established by a NOE, allowing for calibration of distances and assessment of the secondary structure. The Gibbons paradigm became generally known as the 'sequential assignment method' (usually cited without reference to its inventor) and proved to be the method of choice for assignment and definition of secondary structure in small proteins (MW < 6–10 kD). It breaks down when overlap is too extensive or when coupling becomes unobservable at higher molecular weights. In favorable cases it can be replaced by a NOE-based paradigm, which we have devised more recently,¹⁷ or by the heteronuclear 3D and 4D techniques developed in particular by the groups of Bax,³⁸ Laue,³⁹ and Oschkinat.⁴⁰ Still, the initial impact of NMR protein structure determination in the early 1980s was due largely to the widespread successful use of the Gibbons paradigm.

By the time Gordon Roberts and I completed our 'NMR in Molecular Biology' in the spring of 1981,¹ it was possible to formulate the general rules for NMR studies of protein structure and dynamics. Delopierre et al. had calibrated NOEs reflecting the tertiary structure of lysozyme.⁴¹ Earlier, Kuntz et al. had pointed out that a sufficient number of imprecise distances can be a powerful constraint on possible structures.⁴² Later in 1981 we proposed the first folded protein structure ever proposed solely on the basis of NMR data—that of the *lac*-repressor headpiece.⁴³ By 1980 we had established that the headpiece was about 70% helical and were then able to define the contact between the N- and C-terminal helices on the basis of long-range NOEs. The middle remained ill-defined until Zuiderweg et al. applied the Gibbons paradigm and achieved a complete sequential assignment and definition of the secondary structure in 1983.⁴⁴ This allowed us to complete the model which was published in 1984.⁴⁵ In 1985, Kaptein et al. published the refinement of a similarly handbuilt model by restrained molecular dynamics, unfortunately with no reference to our prior work.⁴⁶ The new fashion was to regard model building as an inadequate method for defining NMR structures. However, when a careful comparison was made between the handbuilt model and structures calculated by other methods (in part provided by the Kaptein group), the backbone folds were identical and the average RMSD of atomic position between any of them was less than 2.5 Å—a

typical scatter for modest data sets attainable at that time.⁴⁷ The lesson to be learned from this is that computational methods may improve the fit within the structure, but the essential step in deriving a structure from NMR distance constraints is model building.

The 1980s will probably go down in history as the gold rush era of protein NMR, with boundless enthusiasm, confusion of basic concepts, rediscovery of known facts, and aggressive staking of personal claims. The impression became widespread that 'the NMR method for protein structure determination' has just been invented and allows a 2D FT spectrum to be almost automatically transformed into a structure of crystallographic quality by simple algorithms. Yet the fundamental difference between X-ray crystallography and NMR remains standing. In crystallography one can *calculate* a structure from the diffraction pattern by Fourier transformation. In NMR no such transformation exists. Subjective judgments on the relationship between the NOE, the internuclear distance, and the relevant spectral density function must precede all model building. It is the indeterminacy of these relationships that prompted me to point out at the outset of the structure determination era⁴⁵ that in a strict sense a *determination* of a structure from spectroscopic data was impossible in principle. Still, remembering that one is dealing with approximate structures derived from approximate data, on the basis of a set of subjective assumptions, the approximation can be very good.

While the determination of small protein structures by NMR became commonplace in the mid-1980s, our attention shifted to the two major unsolved problems: (1) the development of methods for defining the structure and function of larger, functionally more interesting protein systems and (2) defining the accuracy of NMR structures. For the first we chose the *trp*-repressor (25 kD)–operator (12 kD) system from *E. coli*, controlled by the amino acid tryptophan. It was the smallest complete allosteric system available and was given to us by its discoverer, Charles Yanofsky. We could predict that the then existing methods—spectroscopic as well as computational—would fail for larger structures. The limitations of spectroscopy were overcome by resorting to extensive isotopic spectral editing. The computational problems proved more formidable. To add to the already existing distance geometry methods, originally introduced by Havel, Crippen, and Kuntz⁴⁸ and restrained molecular dynamics, introduced almost simultaneously by the groups of van Gunsteren and Karplus,⁴⁹ we developed PROTEAN and the use of optimal filtering.⁵⁰ The philosophy of PROTEAN differed from the preceding two in that it was based on an exclusion paradigm—systematically generating a set of structures and retaining all that satisfied a given set of constraints, without optimization. This has the advantage of reducing optimization bias, which for small structures may be inconsequential, but can significantly distort larger structures through the accumulation of errors, unless one begins with a reasonably accurate starting structure. To evaluate accuracy, we compared the performance of all three types of methods.⁵¹ All three types of methods can reproduce the fold of a 'gold standard' structure to a first approximation equally well. But the mean structures calculated by different methods differed by an RMSD of about ± 1 Å from each other, even though the precision of the family of structures calculated by any given method was of the order of 0.5–0.7 Å. Clearly, each method introduces its own bias and more comparisons of this type are

Figure 3 A three-dimensional structure of the *E. coli* *trp*-repressor/ODNA complex calculated from NMR experimental constraints

needed. In the meantime, we cannot claim a greater *accuracy* for NMR structures than ± 1 Å even if the *precision* appears greater.

The study of the *trp*-repressor system also brought home the old dilemma—that one must understand the dynamics of the protein before one can determine its structure by NMR, and vice versa. The protein is a dimer of two chains, consisting of six α -helices each. It binds to DNA in the presence of the corepressor tryptophan, but the ternary complex dissociates if the tryptophan ligand is removed. Only the first three and the last helices in the two chains are well defined by NMR in the free protein.¹⁷ The fourth and fifth are well defined only in the DNA complex, where they form a helix-turn helix with most of the contacts responsible for DNA sequence recognition. Detailed study of backbone proton exchange and relaxation behavior led us to a more complicated picture. The structure of the free protein is relatively unstable. Binding of *trp* stabilizes it and especially the DNA-binding helix-turn helix, which however still remains relatively unstable—being about 90% of the time in helical and 10% in an unfolded form. Binding to DNA stabilizes it further, but the lifetime of the DNA complex remains on the same timescale as the lifetime of the helices in the DNA binding domain. The structure of the complex, the largest structure thus far determined by NMR, is shown in Figure 3. The long path from the 1957 ribonuclease spectrum to this result has justified itself.

The interplay between protein structure and protein dynamics and the potential functional role of dynamics are only now beginning to be investigated and understood. As molecular dynamics (MD) simulations of proteins became feasible in the mid-1970s, it became clear that *in principle* they could provide all the information necessary to calculate all relaxation parameters on proteins and characterize all conformational states and

conformational averaging. This would allow more accurate estimates of internuclear distances on which all NMR structure determinations rest and correctly account for all averaged NMR parameters. Yet it also became increasingly clear that *in practice* this would require potentials far more accurate than any available even now and computations longer by about six orders of magnitude than any that can be carried out on the most modern computers. Clearly, *in practice*, MD will not give us an answer in the foreseeable future. The problem of structural interpretation of NMR data has therefore also been solved only in so far as motional problems and averaging can be ignored.

The best correction for fast motions we found is an empirical estimate of the spectral density functions for vectors of known length (e.g. from ^{13}C measurements for CH bonds). These could then be used for the calculation of unknown distances in the surroundings. Not quite correct, but it is better than ignoring dynamics.⁵² We had explored the use of this approach in the early 1970s in our T_1 , T_2 , and NOE studies of carp parvalbumin.³³ The approach can be exploited to its fullest now that a complete set of sequential assignments and *experimental* values of spectral density functions can be obtained by the strategy of Peng and Wagner.⁵³

It is now also becoming possible to begin to account for such experimentally determined individual spectral density functions correctly.⁵⁴ The inadequacy of simple models for describing protein or nucleic acid dynamics has been repeatedly demonstrated in the 1970s.¹ One relaxation parameter always yields a single correlation time, but seldom could one find a combination that would simultaneously account for all three— T_1 , T_2 , and NOE. The model-free formalism King and I introduced in 1978 rigorously defined the information content of a set of relaxation parameters, but proved unappealing because the set of calculated frequencies and normalized amplitudes could not be simply related to motional parameters without introducing information extraneous to NMR. In 1982 Lipari and Szabo⁵⁵ proposed that the first two terms of our expansion could be given physical meaning by assuming that only isotropic tumbling and fast internal motions mattered. The latter could then be described by an effective correlation time and an order parameter. Although still called model-free, this was in fact a very restrictive model. With a limited number of relaxation measurements this 'model-free' model enjoyed some initial success—but as more extensive relaxation measurements became possible, its inadequacy became evident.^{54,56} Realistic specific models of protein motions based on searches of the conformational space by MD and Monte Carlo techniques can now be constructed, and a more accurate picture is beginning to emerge.

The *trp*-repressor system—where ^1H exchange and ^1H relaxation data indicate that the DNA-binding helices are unstable on the millisecond timescale and ^{15}N relaxation data indicate that on the nanosecond scale they are *not* unstable, where NOE data suggest that the helices are disordered and chemical shift data indicate that they are *not* disordered—well illustrates the complexity of NMR findings we can expect as the method becomes applicable to larger proteins with more complex functions than small globular structures or protein fragments. It may well serve as a paradigm for future work.

NMR is today a mature technology for the study of macromolecular structure and dynamics, alongside X-ray diffraction, as envisioned three decades ago. After nearly a

decade of overstatements about NMR as a structural tool at the expense of dynamics, we are returning to the basic insights about its role expressed in our book in 1981: '... in structural investigations of molecules in solution NMR should be regarded as a method that defines a class of possibilities more often than it permits the proof of a single structure. Interpretation of NMR findings is as much a matter of judgment as a matter of calculation. ... NMR does not derive its importance as a method in molecular biology from being a technique in which one can routinely proceed from the measurement by straightforward calculation to a definite answer. ... The importance of NMR rests rather on the fact that it provides a much greater wealth of clues on questions of structure, *dynamics and function* than other methods.'

Current research interests: structure dynamics and function of proteins involved in regulatory processes; the mechanism of action of *trp*-repressor; use of high-resolution NMR spectroscopy and other physical methods to define mechanisms of conformational transitions and protein folding.

Jeener, Jean: Reminiscences about the Early Days of 2D NMR

Jean Jeener

Université Libre de Bruxelles, Brussels, Belgium

When I started an NMR research group in Brussels in the early 1960s, my aim was to perform clear experiments in connection with the major theoretical effort of the Prigogine group (also in Brussels) on the statistical mechanics of irreversible processes. For this purpose, we started looking at NMR (and pure NQR) in ‘simple’ solids (LiF, CaF₂, gypsum, Pb, NaClO₃ . . .) using coherent pulse techniques, and spent much time building spectrometers and working on spin thermodynamics and spin–spin coupling energy. Our favorite techniques were to transform the order available under complete equilibrium conditions (Zeeman or pure quadrupolar) into spin–spin order via a pair of pulses (appropriately timed and phase-shifted: the ‘Jeener–Broekaert’ sequence), and to look at the state of the spin system somewhat later on by means of a third pulse and quadrature detection of the FID.^{1–3}

In the late 1960s, many experiments had been performed in different laboratories on liquids and solids in which the spin response was studied after a sequence of two (or more) pulses, with the variable separation between these pulses (or the duration of a pulse) as the essential parameter. A well-known early example of such an experiment with a strong flavor of today’s 2D NMR is the observation of *J* couplings in liquids by Hahn and Maxwell in 1952.⁴ With this in mind, one may wonder why the double Fourier transform was not used earlier as a systematic tool for processing the data from experiments involving multiple time delays. First, there were the difficulties which slowed down the development of ‘single’ Fourier transform methods: no phase sensitive detection in early pulse spectrometers (hence, nonlinear detection), long dead times, slow ADC, no computer in the laboratory, etc. Also, multiple pulse experiments seemed so complicated, particularly in solids, that one was tempted to treat the various delays separately whenever possible.

Two souvenirs come back to my mind, illustrating the generally incomplete intuitive understanding of Fourier spectroscopy at a time where this was already the accepted technique in high-resolution NMR. The first begins with a lecture which I gave at the Waterloo (Ontario) NMR Summer School, in 1969 or 1971, advocating the use of quadrature detection in solid NMR, in which I casually mentioned that quadrature detection would improve the signal-to-noise ratio by a factor of $\sqrt{2}$ in high-resolution FT NMR. The next Sunday evening, at the opening of the NMR Gordon Conference, I was caught in a circle of excited NMR friends who strongly opposed this latter ‘Waterloo’ statement on the mistaken ground (as I recall) that the same noise was fed to both phase sensitive detectors, hence the corresponding outputs had to be strongly correlated. At this point, I realized the difficulty of ‘proving’ something which looked obvious to me, and I was glad to feel the moral support of people like Hahn, Waugh, and Redfield, watching the event from a distance, while I was struggling to defend

my views. The second is the surprising unwillingness of the instrument manufacturers to provide quadrature detection on their NMR pulse spectrometers for many years, in spite of strong insistence from many physicists.

At that time I became interested in extending our work on protons in gypsum⁵ into a study of molecular motion in liquid crystals by measurements of the relaxation matrix (mainly spin–lattice relaxation). For this purpose I tried to cook up a pulse scheme which would give results of the type presently given by NOESY, making dreams resembling stochastic NMR. This led to the design and construction of a fancy digitally controlled pulse generator, but was otherwise in vain except for the impression that if a suitable scheme emerged it would be plagued by the coherent response caused by the multiple pulses. Almost in despair, I started investigating this latter problem with the help of Gerrit Alewaeters,^{6,7} initially on the simple case of the standard AB spectrum in liquids. This soon led to the general proposal of 2D FT NMR spectroscopy in the simple case of homonuclear COSY without phase cycling. We tried to observe the effect experimentally on ethylbenzene, spending weekends working with the rather primitive FT spectrometer available in organic chemistry at our university. Due to the bad phase stability of this spectrometer and to our total lack of practice of high-resolution NMR, Gerrit Alewaeters could only observe some of the strongest cross peaks of the 2D spectrum with a signal-to-noise ratio just high enough to confirm that our quantum mechanical predictions were correct (not really a surprise . . .), but too low to make the new technique look very usable. Formal publication was deferred until cleaner experimental confirmation would be available, but I kept spreading the idea by personal contacts, lectures (probably for the first time at the AMPERE Summer School in Baško Polje in 1971), and by circulating ‘unpublished’ notes written in November 1971.⁸ Soon, Richard Ernst let me know that his co-worker Baumann had brought the 2D FT idea back from Baško Polje to Zürich, and that the Zürich group intended to work on it. As it turned out, one of our recurrent delights in Brussels for a number of years has been receiving news from Zürich about the progress of 2D NMR, both experimental and theoretical. It was also a pleasure to learn about the new 2D FT ideas developing in many other groups.

In 1977, Richard Ernst was describing the many different ways of using 2D NMR in such a clear and systematic presentation that it soon struck me that my original goal, investigating spin–lattice relaxation, was absent from the list but could be implemented ‘easily’ (by the method now called NOESY, much simpler than my original dreams). I mentioned this to Ernst at the NMR Gordon Conference. He asked whether we intended to develop the method in Brussels; the answer was ‘no’ for lack of practice and of suitable instrumentation, and I was delighted to accept the proposal of developing NOESY as a joint project between Zürich and Brussels.⁹

Since that time, I have always kept a part-time interest in 2D NMR and its variants. I learned the ‘superoperator’ technology in an attempt to provide a suitable tool for 2D peak-shape analysis,¹⁰ and Marianne Koenig demonstrated that this is indeed a viable method for the study of the rate of chemical reactions under favorable circumstances.¹¹ More recently, I have become interested in the collective effects of radiation damping and dipolar field in 2D NMR, and I

am participating in the present controversy about the suitable theoretical presentation of these effects.

Johnson, Charles S. Jr.: The Evolution of Ideas about Optical Analogies to PFGNMR and the Visualization of PFGNMR Experiments

Charles S. Johnson, Jr.

University of North Carolina, Chapel Hill, NC, USA

In the period 1974–84 we were concerned primarily with dynamic light scattering (DLS) and holographic relaxation spectroscopy (HRS) for the measurement of diffusion and electrophoretic drift. The HRS experiments are particularly easy to visualize.¹ Concentration patterns (or gratings) of photoproducts are created by photoexcitation with crossed laser beams, and the patterns are smeared out by diffusion and translated by flow. The time evolution of a pattern is detected directly by monitoring the efficiency with which it diffracts light from a weak probe laser beam. However the experiments are not easy and the amount of information obtained is limited. Furthermore, photochemical reactions often complicate the interpretation of data.²

We also worked with complementary pulsed field gradient NMR (PFGNMR) experiments,³ but we did not make use of the underlying similarities between DLS and PFGNMR. Of course, I had seen Mansfield's paper on NMR diffraction and microscopy,⁴ and I knew that the magnitude of the optical scattering vector q and the area of the gradient pulse ($\gamma g \delta$) played similar roles; but my grasp of the optical NMR analogy was far from complete. What was needed was time for reflection. It was fortunate that I was able to begin a sabbatical leave in January 1985 in the laboratory of R. R. Vold and R. L. Vold (Bob and Gitte) at La Jolla. In that pleasant atmosphere I spent half of my time writing papers on HRS and the other half on computer simulations of PFGNMR experiments involving flow.

A particularly important instance for me occurred when Alex Pines invited me to Berkeley to give a seminar on HRS. He picked me up at the Oakland airport, and we talked about light scattering and NMR on the way back to Berkeley. I clearly remember him commenting that a spin echo is analogous to a diffraction spot. We talked about short T_2 storage experiments and stimulated echoes. I am not sure that I actually learned anything new in that conversation, but it focused my thoughts on the connections between PFGNMR, NMR imaging, and optical diffraction.

Meanwhile back in Chapel Hill, Tim Saarinen started work on PFGNMR as the, somewhat isolated, NMR person in my light scattering laboratory. The goal of his thesis project was to combine electrophoresis with PFGNMR to develop electrophoretic NMR (ENMR). This experiment was expected to be similar to electrophoretic light scattering (ELS) but with the advantage of selectivity based on chemical shifts. The ENMR project went slowly because we did not have

Figure 1 Magnetization helices. The isochromats (vectors) represent the magnetization of evenly spaced layers of the sample in the direction of the gradient. (Taken from Ref. 6)

a dedicated NMR spectrometer; and we had to share the departmental Bruker WM-250, an instrument that seemed to have more down time than up time. Tim finally resorted to carrying his gradient probe and current driver to a spectrometer 15 miles away at the Research Triangle Institute.

This was an exciting (and frustrating) time in the laboratory as Tim designed and tried to interpret gradient experiments while learning the theory of PFGNMR. He had a new idea almost every day, and he forced me to think hard about gradients and NMR. We often argued about theory and interpretation, and discovered that the new idea was an old idea in disguise, e.g. z magnetization gratings (new) and the stimulated echo experiment (old). However, a very useful picture of the PFGNMR experiment evolved. This picture was based on the idea that magnetization gratings can be created that are analogous to the concentration gratings in HRS. In fact, Tim obtained an image of a magnetization grating and used it to calibrate a magnetic field gradient. I do not remember the exact sequence of events, but I believe that Tim was the first to talk about magnetization ribbons composed of isochromats for different layers of a sample after a 90° rf pulse, and the twisting of the ribbons into helices by constant magnetic field gradients. He presented the transient magnetization gratings (TMG) for the measurement of diffusion and flow at the 1987 ENC⁵ and we published the details in 1988.⁶

An illustration of the winding and unwinding of magnetization helices from that paper is shown in Figure 1. The sample is prepared by a 90° rf pulse at $t = 0$. This is followed by a gradient pulse of duration t_w that sensitizes the magnetization to translational motion of the spins. Diffusion and flow during the time interval t_f produce attenuation and translation of the helix, and sometime during this interval a 180° rf pulse changes the signs of the phase angles. A second gradient pulse then refocuses the isochromats to form an echo at time $t_w + t_f + t_r$. The Fourier transform of the echo signal with respect to t_r produces an image of the magnetization grating.⁶ The *spatial manipulation of magnetization* (SPAMM) method now used in MRI for the measurement of flow is an important application of TMGs.⁷

The winding up of helices and the effects of diffusion and flow on helical magnetization patterns captures the essence of PFGNMR, and provides a better illustration for constant gradients (linear magnetic field change) than the spherical plots traditionally used in this field. This intuitive picture of helices or spirals is also useful. For example, Paul Callaghan

told me that he thought of *modulus addition through spatially separated echo spectroscopy* (MASSEY) after seeing the pictures of helices being unwound.⁸ In fact, the magnetization ribbons and their behavior under the influence of rf pulses and gradients provide insight about the essential features of all gradient experiments.

It turns out that the stimulated echo (STE) experiment with a constant gradient is directly analogous to diffraction by a transmission grating.⁹ The first two 90° rf pulses in the presence of a magnetic field gradient prepare a spatial grating of the *z* components of nuclear magnetization. The third 90° rf pulse then converts the *z* grating into a grating of transverse magnetization. It is this planar cosinusoidal pattern that is twisted by a gradient to produce the stimulated echo, and the vector addition of isochromats to form the echo¹⁰ is similar to the addition of electric field vectors to produce a diffraction spot.¹¹ The wonderful thing about PFGNMR is that all of the lines in the NMR spectrum can be unraveled from the echo to reveal their associated diffusion coefficients and flow rates.¹² This forms the basis of 2D ENMR^{13,14} and the more recent diffusion-ordered 2D NMR (DOSY)¹⁵ that were outgrowths of the transient gradient idea in this laboratory.

I hasten to add that the diffraction analogy was stressed by Mansfield in his first paper on NMR imaging¹⁶ and optical analogies have influenced many others working in magnetic resonance imaging (MRI).¹⁷ The idea that a single rf pulse can produce an echo for a layered sample was clear from imaging experiments. Also, in retrospect, the pioneering work of Tanner and Stejskal,¹⁸ especially as it related to restricted diffusion, is filled with analogies to diffraction. However, I am not aware of the use of gratings and helices in the interpretation of PFGNMR diffusion and flow experiments prior to Saarinen's work. Of course, all of this appears obvious and even trivial now. It really is remarkable that NMR imaging was not discovered until 20 years after Hahn's papers on free induction and spin echoes.^{19,20}

Johnson, LeRoy F.: My Early Days in NMR Spectroscopy

LeRoy F. Johnson

Cupertino, CA, USA

My career in NMR began in July 1957 when I was hired by Varian Associates in Palo Alto. I was to be an applications chemist working for Jim Shoolery in Martin Packard's instrument division research group. By then, Varian had developed the NMR product line to the level of an HR-40 instrument, which consisted mainly of a water-cooled electromagnet with 1.5 kV, 1 A current-regulated power supply, galvanometer/flux-stabilizer system, slow-sweep unit, rf unit, spinning sample tube probe, and a 6-in. strip chart recorder. Not having the benefit of field shim coils or even a ratchet magnet bender, resolution was optimized by moving the probe in/out and up/down using a two-axis screw drive probe holder. This optimizing became a daily chase in search of the 'sweet spot' as the room temperature made its diurnal change in the non-air-conditioned lab.

The HR-40 grew into the HR-60 and refinements such as magnet cooling water temperature control, magnet thermal insulation, and field shim coils improved long-term stability and provided a higher level of performance with greater sample throughput.

Short-term stability was still a problem, and it was not until the A-60 came into existence in 1961 that a new level of performance was achieved with the use of an NMR lock signal. An external sample of water in the A-60 probe provided a signal which could be used to tie together magnetic field and rf frequency fluctuations. This field/frequency lock provided a very great increase in spectrometer stability, and for the first time permitted scans to be plotted on precalibrated chart papers using a flat-bed recorder.

The new level of stability also provided some improvement in sensitivity, since it was now possible to sweep more slowly through the spectrum while using more rc filtering to remove higher frequency noise components. However, owing to the presence of what amounts to baseline wander, it was not possible to gain much sensitivity with the slow sweep method.

In the summer of 1962, Dr. Leland Allen of Princeton University Chemistry Department visited the Varian applications lab in order to try out a new method for sensitivity improvement. He proposed to increase the signal-to-noise ratio by using repetitive scans through a spectral region using normal sweep rates or even somewhat faster than normal. Results from each scan would be converted from the voltage that was normally sent to the plotter to counts through use of a voltage-to-frequency converter. It was necessary then to separate the spectral region into discrete channels, and somehow to store the counts obtained from each scan. The NMR signals would *coherently* add as counts from each scan were added into each channel. Random noise would also add, but *incoherently*. The result would be an increase in signal-to-noise proportional to the square root of the number of scans.

Figure 1 Top: Normalized sum of 100 sweeps of 0.2% ethylbenzene in CCl_4 . Bottom: A single 4-min trace with a Varian A-60 spectrometer

A device well-suited to the task was then available from the Mnemotron Company, a subsidiary of Technical Measurements Corp. The CAT (computer of average transients) model 400 combined a voltage-to-frequency converter, 400 channel analyzer, timing circuits, a digital-to-analog converter, and a small oscilloscope display in one package. Repetitive sweeps through the spectral region of interest were made by appropriately setting the A-60 sweep width, sweep rate, and offset adjustments and then repeating the forward scan and quick back scan functions by using microswitches which would be tripped as the recorder arm moved and generated the sweep. In order to initiate data accumulation reliably a sideband from a TMS signal was generated by a tunable audio oscillator which would be triggered off as soon as data accumulation started. Part of my contribution to the project was the design and construction of the triggering circuitry to control all this, resulting in what came to be known as the CAT box. Counts stored in each channel were converted back to voltage suitable for output to the small oscilloscope or to the A-60 plotter by the digital-to-analog converter.

We were able to demonstrate that as much as a factor of 50 in signal-to-noise improvement could be achieved using overnight data accumulations. Figure 1 is taken from our communication describing the method.¹

The method was refined and led to the development of the Varian C-1024 time averaging computer with 1024 channels and built-in voltage sweep ramp with adjustable fly-back rate. This accessory was ultimately connected to different makes and models of NMR spectrometers, and chemists were soon exploiting the benefit of digitized NMR spectra.

Digitization of free induction decays generated by pulsed rf excitation followed by Fourier transformation was yet to come.

Jonas, Jiri: NMR and High Pressure

Jiri Jonas

University of Illinois at Urbana-Champaign, Urbana, IL, USA

Looking at the title of this article, one could conclude that I want to discuss the highly competitive way we do NMR research these days. In spite of a strong temptation to do so, however, I will describe instead my attempts to use pressure as an experimental variable in NMR experiments. Before I start my story, I would like the reader to know that my initial motivation to enter the magnificent field of NMR was not completely pure. We have to go back to 1959 in Czechoslovakia to understand the situation. I figured that, because no respectable high-resolution NMR was then done in the former Soviet Union and other Eastern-bloc countries, NMR spectroscopy would be my ticket to the West and preferably to the mecca of all displaced persons—the United States. It really did work!

Thanks to a prominent organic chemist from the University of Illinois, Roger Adams, who visited our neophyte NMR laboratory in Prague, I was lucky to land in Herb Gutowsky's laboratory at the University of Illinois at Urbana-Champaign in 1963 and started to do NMR spectroscopy seriously. I enjoyed myself very much, as I was contemporary with Adam Allerhand, Nevil Boden, Joe Deck, Bill Derbyshire, Dave Vanderhart, Bob Vold, and many other great students and postdoctoral students in Gutowsky's group. I still remember the NMR course given by Charlie Slichter in the Department of Physics and, I may add, this course is even now, after 30 years, required for my own graduate students. My very first NMR experiments^{1–3} were carried out on high-resolution NMR Varian spectrometers, models A-60 and DP-60. In particular, the shimming of the DP-60 was sometimes quite an adventure. I can well recall the struggles to achieve the best resolution on the DP-60. The use of 'magnet cycling', especially the use of a mechanical field trimmer, was an art that required a lot of practice to master. These procedures for attaining a good resolution on an electromagnet are well described in a 1960 monograph published by Varian Associates.⁴

After several years of doing high-resolution NMR spectroscopy, I was looking for an industrial job, but to my surprise was offered a position as an assistant professor in the Department of Chemistry at the University of Illinois in 1966. I still remember when the Head of the Department of Chemistry and Chemical Engineering, Herb Carter, offered me the position. As a start-up package there was no NMR instrument dedicated for my use, but I was offered a sum of \$8000. Carter told me not to use these funds for a summer salary and also advised me not to spend it all in one place! After some soul searching, I purchased a Tektronix storage oscilloscope and the departmental electronic shop built a trapezoidal sweep generator for me; I was on my way to measuring relaxation times via the adiabatic fast passage (AFP) technique.⁵ For my work I was using a departmental Varian DP-60 high-resolution NMR spectrometer either at night or on weekends, whenever this instrument was not used for routine service.

For the benefit of the current generation of NMR researchers, I may add that extracting a single T_1 value represented a laborious process. First, I had to calibrate the H_1 field and the sweepwidth and determine whether the AFP conditions were satisfied.⁵ Then I had to record several oscilloscope traces for different settings of the waiting time. In spite of the lengthy procedures to generate the T_1 data, I succeeded with the help of an undergraduate student, Tom Digenarro, in finishing several NMR studies of the dynamics of motion in polyatomic molecular liquids.^{6–8}

These studies dealt with anisotropic reorientation of selectively deuterated methylacetylenes⁸ and phenylacetylenes⁷ in the liquid state. Of particular interest was the finding that for methylacetylene- d_1 the dipole–dipole interactions provide the dominant relaxation mechanism for methyl proton relaxation at lower temperatures, whereas at higher temperatures the contribution of the spin–rotation interactions could be detected. This finding led us to systematic experiments on liquids where the spin–rotation interactions represent a major relaxation mechanism.^{9–13} The reason for my interest in spin–rotation interactions in liquids was related to the fact that, by studying nuclei relaxed by spin–rotation interactions, one can learn about angular momentum correlation times, which together with the knowledge of reorientational correlation times permit a more detailed characterization of the nature of molecular motions in liquids; for example, one can find out whether one is dealing with a small-step or large-step rotational diffusion.

Since I intended to carry out systematic studies of the dynamic structure of liquids, I realized that any serious experimental attempts to characterize the molecular dynamics in a liquid must include the separation of the effects of density and temperature on molecular motion. Most NMR studies of liquids have used temperature as the only experimental variable, while pressure was left constant, usually at atmospheric pressure. Such studies probe only a narrow region of the liquid state since, for any given temperature, a liquid can exist over a range of densities. The use of pressure provides another dimension over which to investigate the liquid system. It is important to realize that changing the temperature at constant pressure affects molecular motion in two distinct ways: not only is the average kinetic energy of the molecule changed, but there is always an accompanying change in the average volume available for the motion of the molecule. If one uses both pressure and temperature as experimental variables in an NMR experiment, only then can one separate the effects of density and temperature on molecular motion.

At first it would appear that the change in density for a liquid over the typical experimental range ($\sim 100^\circ\text{C}$) is insignificant; however, for a molecular liquid, an increase of 30°C requires the pressure to be increased approximately 40 to 60 MPa (1 bar = 0.1 MPa) to maintain a constant density. Very often the temperature effects on the dynamics of molecular motions are much smaller than the combined density–temperature effects, and in many cases volume effects play the dominant role in influencing motions in the liquid state. This is physically quite reasonable because the molecules are so closely packed in the dense liquid that the forces between particles rise almost exclusively from the harsh short-ranged repulsive forces between nearest neighbors. Therefore, even small changes in density can produce a considerable change in the molecular dynamics of the system.

To my surprise I found out that several high-pressure NMR studies had already appeared. These early high-pressure NMR studies of solids, liquids, and gases were reviewed by Benedek¹⁴ in his brief monograph dealing with NMR at high pressure. In addition, McCall et al.^{15–17} reported the pressure dependence (up to 70 MPa) of the self-diffusion coefficient in several liquids at room temperature, using the spin echo method. However, these early studies used equipment with no provision to keep the samples oxygen free, nor did they allow high-resolution operation.

Since my goal was to carry out systematic studies of various NMR relaxation times in molecular liquids, it was important that I develop a high-pressure NMR probe with the following performance features: (a) wide pressure and temperature ranges; (b) large sample volume; (c) reliable high-pressure rf feedthroughs; (d) contamination-free sample cell; (e) ease of assembly; and (f) high-resolution capability. The original design^{18,19} proved quite versatile as in later years we used its modified versions to carry out high-pressure NMR experiments on solids and polymers,^{20–22} high-pressure experiments at high temperature,²³ and experiments up to 1 GPa (1 GPa = 10 kbar); we were even able to introduce a mixing device for the study of homogeneous catalytic reactions.²⁴ The modified version of the original NMR probe¹⁹ is used even now in our high-pressure NMR studies of biochemical systems.²⁵

A major change in my research lifestyle occurred in August 1970 when I purchased from Varian Associates the high-resolution magnet system consisting of the V-3800-1 electromagnet with 3.8-in air gap and all accessories such as a heat exchanger and a flux superstabilizer. The wide gap of this 1.4 T electromagnet provided us with enough working space so that we could optimize the design of high-pressure NMR probes. In addition, the acquisition of the high rf power pulsed NMR spectrometer made by NMR Specialties, Inc. was another major improvement of our experimental capabilities.

Between 1967 and 1973 I was fortunate to have quite a number of excellent graduate students such as Roger A. Assink, Tom E. Bull, Jack DeZwaan, Yunko Lee, Nan-I Liu, Sam Seymour, and David J. Wilbur. In 1970, Bull and I published our very first high-pressure NMR study of liquid acetone.²⁶ We were able to follow the effects of pressure on the intramolecular and intermolecular dipolar relaxation in this liquid by using isotopic dilution T_1 experiments on acetone in acetone- d_6 at elevated pressures. This initial experiment was followed by other studies dealing with pressure effects on anisotropic reorientation in liquids,²⁷ on spin-rotation interactions,¹⁰ and on reorientational motions in several selectively deuterated liquids²⁸ and by high-resolution FT NMR studies of fluids at high pressure.²⁹ All these studies were reviewed in my article³⁰ which appeared in 1973 in *Advances of Magnetic Resonance*, edited by John Waugh.

Instead of discussing in detail all the various results we obtained by using pressure as an experimental variable in our NMR experiments, I shall focus on several specific studies whose results led to significant developments in later years. For example, Wilbur and I reported²⁹ that it is possible to achieve a high homogeneity of the magnetic field over the nonspinning sample (0.8 cm diameter) at high pressure (500 MPa). As a result, for the first time we were able to use the Fourier transform technique to obtain high-resolution spectra of various liquids or liquid solutions at high pressure.^{29–32} In

addition, we predicted the promising future of this FT high-pressure and NMR approach in other fields. However, the main applications^{25,33,34} were delayed until high homogeneity super-conducting magnets equipped with superconducting and room-temperature shims became available commercially.

This high-pressure FT NMR technique,²⁹ together with the general results of our systematic experiments^{35–38} dealing with the applicability of hydrodynamic equations at the molecular level, allowed us to carry out a series of experiments^{39,40} that for the first time provided the experimental evidence of the so-called Kramer's turnover for reactions in liquid solutions. The technique also resulted in observation of the energy-controlled regime for organometallic systems,⁴¹ thus demonstrating the existence of the so-called heavy metal atom bottleneck effect⁴² which reduces the intramolecular energy transfer. In this connection, let me stress the importance of using pressure as an experimental variable in the studies of dynamical solvent effects on reaction rates, because the collision frequency that reflects the coupling of the reaction coordinate to the medium can be related through simple hydrodynamic arguments to shear viscosity. In most studies, shear viscosity is changed by using different solvents, but in high-pressure experiments viscosity can be changed by changing the pressure. Viscosity represents only an approximate measure of the degree of coupling of the reaction coordinated to the reaction medium. Consequently, by changing solvents one may influence the reaction rate by different molecular shape, size, or strength of the intermolecular interactions of the solvent molecule used. Therefore, different solvents of the same shear viscosity may not have the same effect on the reaction rate measured. Clearly, using the same solvent and changing its viscosity by pressure represents a much cleaner experiment. Because most of the studies of simple isomerization reactions involve laser spectroscopic techniques, let me also comment on the relative merits of the NMR technique. There are several advantages in using NMR to study isomerization and hindered rotation in liquid solutions. The system chosen can be very simple and the molecule can be studied in its ground state. For example, the chair-chair isomerization of cyclohexane⁴⁰ is a relatively simple process that can be characterized by two degrees of freedom.

Another good example of an early high-pressure NMR study whose results motivated further successful research efforts was the study of the density effects on the dynamic structure of liquid D_2O .⁴³ These results led to systematic studies of the applicability of the Debye and Stokes-Einstein equations in H_2O and D_2O over a wide range of pressures (up to 1 GPa),⁴⁴ including subzero temperatures⁴⁵ and the compressed supercritical H_2O and D_2O .⁴⁶ As a matter of fact, the general conclusions we arrived at are helpful for us even now in our studies of pressure-induced reversible unfolding of proteins,⁴⁷ because the pressure dependence of the water-water interactions and water-protein interactions plays the dominant role in this process.

The study of the pressure dependence up to 400 MPa of the proton T_1 value in solid adamantane⁴⁸ at various temperature is yet another example of an experiment that led to new developments. Specifically, the large difference between the T_1 value of the orientationally disordered rotor phase of adamantane and the T_1 value for the ordered (brittle) solid phase of adamantane can be used to obtain information about the kinetics of the phase transition.⁴⁹ At a much later date,

we used an analogous approach to study the pressure effects on crystallization kinetics of polyethylene,²² a problem of technological relevance.

Brief though it is, this historical sketch of my early years in NMR covers the period 1963 through 1973. In subsequent years, I have been very fortunate in continuing to take advantage of the fact that 'NMR in chemistry is a true evergreen'.⁵⁰ For a general impression of the NMR studies performed in my research group after 1973, the reader may wish to peruse several key reviews that have appeared since then.^{51–56}

Biographical Sketch

Jiri Jonas b 1932. B.Sc., 1956, Ph.D., 1960, Chemistry, Czech. Acad. Sci., Prague, Czechoslovakia. Postdoctoral work 1963–66 at the University of Illinois with Herb Gutowsky. Professor of Chemistry, University of Illinois, Urbana, IL, USA, 1966–present. Approx. 280 publications. Research specialties: NMR spectroscopy at high pressures; dynamic structure of liquids, biochemical systems, and disordered solids.

Kaplan, Jerome I.: Chemical Exchange in Various Guises

Jerome I. Kaplan

Indiana University Purdue University Indianapolis (IUPUI), IN, USA

I graduated in theoretical solid state physics from the University of California, Berkeley in 1954 and immediately took a position at the Naval Research Lab (NRL), Washington, DC. Some time in 1955, C. Pekeris of the Weizmann Institute gave a talk at NRL. Someone at the lab heard that I had expressed an interest in visiting Israel, so it was arranged that I would drive C. Pekeris back to the train station. On the way it was arranged that on application I would be able to obtain a Louis Lipsky fellowship to The Weizmann Institute.

I left NRL in the spring of 1955, hitchhiked around Europe for three months—ending up in Naples. From there I took a boat to Israel. At the Weizmann Institute I lived in housing on the campus and ate at the campus cafeteria (this monastic existence allowed me to save money for my subsequent trip through Asia). There was no Physics Department at that time, so I was listed as a member of the Applied Math Department and assigned to work with Saul Meiboom—the NMR guru.

My only memory of the working environment was a large room with a magnet and racks of electronics. The various switches on the electronics were unmarked, and I was told by Saul Meiboom that those using the equipment knew what each switch did and those who did not know should keep their hands off. I did though get an opportunity to finger-rotate the sample holder, which miraculously lengthened the FID. The lab practice was to obtain the ‘same’ result by using a windshield wiper motor.

Saul Meiboom shortly after I arrived gave me the problem I was to work on. The Hamiltonian for the nuclear spin system of molecule A is given as

$$\hat{\mathcal{H}}_A = \sum \omega_{0i} \hat{S}_i^z + \sum J_{ij} \hat{S}_i \cdot \hat{S}_j \quad (1)$$

In the weak coupling limit (where the J values are small relative to the differences in the ω_{0i} values) $\mathcal{H}_A$ can be approximated by

$$\hat{\mathcal{H}}_A = \sum \omega_{0i} \hat{S}_i^z + \sum J_{ij} \hat{S}_i^z \hat{S}_j^z \quad (2)$$

The theory for chemical exchange in the weak coupling limit had been worked out by Gutowsky, McCall, and Slichter (GMS). My problem was to develop a general theory for chemical exchange for strong coupling. I remember immersing myself in this problem for about a month without any feeling that I was getting closer to its solution. Being very frustrated, I decided to take a day off and sit around the lab watching the on-going experiments. While passing the time, I glanced at a journal article. Something there was the missing clue, for I suddenly realized I knew how to formulate chemical exchange for strongly-coupled systems.¹

I worked on two other NMR problems while I was at the Weizmann Institute: one was a mathematical description of

how the sample holder rotation modified the FID² and the other was the calculation of the double quantum absorption. Here one obtains the double photon absorption peak midway between the two single photon peaks, ω_{0A} and ω_{0B} . I worked out the theory and Saul Meiboom verified the effect experimentally.³

In the lab over most of my stay were three graduate students—Shlomo Alexander, David Gil, and Aharon Lowenstein. They spoke intimately of the War for Independence 1948 and, if memory serves me right, of someone being a classmate of Anne Frank. I traveled a lot about Israel—I had a small Fiat car—but the trips I remember best were trips to Masada—a mesa near the Dead Sea which was the final resting place for a Jewish sect which had held out against the Roman army, and a trip to Eilat—a seashore area near the Red Sea. On these trips we had lots of student company and traveled well armed so as to provide protection against possible terrorist attacks (fedayeen).

There was a short war during my stay during which I was air raid warden of my building (slept through the night while my roommate next door, a Japanese survivor of the bombing of Tokyo, sat out the night in our air raid shelter), dug slit trenches for a local kindergarten, and went with David Gill and another student into the Israeli-temporarily-occupied Gaza Strip by crossing over an unguarded dry river bed. This of course was illegal and we got properly rebuked by the border guard when we left through a normal check point (the Gaza Strip was returned to Egypt the next day).

I left Israel in the fall of 1956 and traveled through Asia for three months. My memory is cloudy but I believe I met H. McConnell in California, where he told me he had put the GMS theory into a Bloch equation form. Thus, when a friend suggested that I quickly send in an abstract to an upcoming meeting, I modified the strong coupling exchange paper written in Israel so it could be expressed in ‘Bloch’ form, and this ended my Weizmann Institute experience.^{3,4}

It was over 10 years after my second paper on chemical exchange that I again became involved with NMR. I had been at the Battelle Institute, Columbus, OH about a year when I called Gideon Fraenkel (Department of Chemistry, Ohio State University) to see if he would give a seminar talk at Battelle. He asked if I were the Kaplan who had written papers on chemical exchange. We immediately got together and collaborated. Our major result was a simplified procedure to obtain the density matrix equations for chemical exchange which we called ‘permutation of indices’.⁵ Exactly who made the suggestion that we write a book on chemical exchange is lost in time (my wife claims she was the instigator). It took us almost two years to complete the book as we had to cover a number of topics not previously described.⁶

I then left Columbus, OH for Indianapolis, IN, where I was employed in a tripartite arrangement: one-third at the Krannert Institute of Cardiology, one-third at the Indianapolis Center For Advanced Research (working mostly on solar energy and medical devices), and one-third in the Physics Department of IUPUI (Indiana University/Purdue University at Indianapolis). My task in the Cardiology Institute was to obtain heart mapping using NMR.

Starting in 1975 we began a search to find an NMR parameter which would distinguish ischemic muscle tissue from normal muscle tissue. Initially we decided to see if T_2 could provide the differentiation, but because of experimental

difficulties we gave this up and switched to T_1 differentiation. We submitted the results to *Science* in July 1977, but the paper was not accepted for technical reasons. A revised write-up was submitted in 1979 to *Journal of Nuclear Medicine* and accepted for publication in 1980.⁷ We found that there existed approximately a 10% difference in water concentration of ischemia as compared with normal tissue. It thus became apparent that to achieve a significant normal ischemic discrimination we would need to work with the T_1 differences rather than the water density differences.

With this in mind, I developed the idea of the inversion recovery procedure. A description of the inversion recovery procedure was given in a manuscript dated August 20, 1979, as received by the *Journal of Magnetic Resonance*. The manuscript was not published. I don't have a record as to why. Subsequently the ideas in the manuscript were published as a US Patent.^{8,9}

Our attempts to obtain good experimental images in our laboratory were not successful, so I cast about for some other laboratory which would permit me to run the inversion recovery procedure. I first contacted Waldo Hinshaw; he was agreeable but could not get approval from Massachusetts General. I then contacted Johns Hopkins, but the group there was temporarily closing down. Finally I contacted Larry A. Crooks at the Nuclear Imaging Laboratory, University of California, San Francisco. He said he could run the procedure.

Thus in the summer of 1980 I went out to the University of Washington, and during the month of August traveled down to San Francisco and during a nail biting two days (August 18 and 19) (equipment was down the first day) was able to obtain one good run.

The samples were first pseudo density sensitized by the inversion recovery procedure and then mapped using the Nuclear Imaging Laboratory standard mapping procedure. I was overjoyed both by the results as well as the surprised looks on the faces of the Nuclear Imaging Laboratory personnel who did not expect to see so much contrast.

The results have not been previously reported as a research contribution because a morphological comparison was never made by the Nuclear Imaging Laboratory, University of California. The image using the inversion recovery procedure is shown in Figure 1 and in Figure 2 is shown the mapping without the inversion recovery procedure.

Figure 1 Image using inversion recovery procedure

Figure 2 Mapping without inversion recovery procedure

It was clear that for heart mapping we needed a much faster method for mapping than was then available. Through an extended period I mulled over a concept from my childhood of summer camp groups spread out on the main floor of Grand Central Station, New York City, who would signal to the station master that they were ready to disembark by singing their camp song. Thus, I imagined mapping could be done by having a unique series of frequencies to be established at each point in two- or three-dimensional space. I developed these ideas and was invited by General Electric to give a talk on the subject in Milwaukee on July 13, 1983. At the end of the talk I was handed a patent by Likes—a General Electric employee—which disclosed how to obtain the unique series of frequencies at each point but failed to disclose how to use this information to obtain an image. I then went ahead and obtained a patent on this concept.¹⁰

Because of circumstances outside of my control, I had no further interaction involving MRI at IUPUI or the Radiology Department of the Indiana Medical School which is on the IUPUI campus.

In 1981, I was invited by Al Garroway to come to the Naval Research Laboratory, Washington, DC, where we worked on MRI imaging of epoxy compounds and on a comparison of the theoretical signatures for homogeneous and inhomogeneous distribution of correlation times for chemical exchange.¹¹ The lack of what I felt was a valid theory for the stretched exponential used in this paper was then the impetus when I came back to IUPUI to formulate 'A Proposed Mechanism for Nonexponential Chemical Exchange'.¹²

Kaptein, Robert: The Early Days of CIDNP

Robert Kaptein

Utrecht University, Utrecht, The Netherlands

The years 1967–68 were a very exciting period. The first reports on chemically induced dynamic nuclear polarization (CIDNP) had just appeared^{1–4} and it was clear that the new phenomenon could be extremely useful for the study of free-radical reactions in solution. However, it was also clear that the first explanations offered^{2,4} could not be correct or at least were incomplete. In particular, the so-called multiplet effect, which denotes the simultaneous occurrence of positive and negative intensities within the multiplet of a spin-coupled nucleus, defied explanation in terms of the dynamic nuclear polarization (DNP) theory,^{2,4} which is analogous to the Overhauser effect. So, there we had these enormously enhanced NMR lines, which could be easily generated by running free-radical reactions in the NMR tube, and for several years nobody had a clue as to how they arose. In the following article I shall give a personal account of the early development of CIDNP and in particular of the birth of what is now called the radical pair theory (for early reviews see Refs. 5 and 6).

The first observation of CIDNP dates long before the 1967 publications. In fact, countless discoveries and rediscoveries have been made, often dismissed as artifacts. An example is that from the laboratory of Prof. Th. J. de Boer of the University of Amsterdam. NMR spectra of a cyclopropyl compound in CDCl_3 had the chloroform line in emission or absorption depending on the operator who ran the spectrum. It turned out that one operator had the habit of shaking the NMR tube before recording the spectrum, while the other had not! The slight amount of oxygen mixed in the solution oxidized the labile cyclopropyl compound, which resulted in polarized CHCl_3 as one of the products of a radical recombination reaction. Since the chloroform proton has a T_1 value of 60 s or so, it is a particularly favorable molecule in which to store nuclear polarization.

The first to observe the CIDNP effect and realize it was not an artifact was probably Joachim Bargon, a graduate student in Darmstadt in 1964. He made an NMR study of polymerization reactions initiated by benzoyl peroxide and discovered a strong negative polarization for benzene. In the hierarchical German system he would never have published these findings on his own, but he had also great difficulty in convincing his supervisor or others that he had hit upon something important. Finally he got Hanns Fischer interested and this led to the first publications of the Darmstadt group.^{1,2} An interesting aspect of the second paper² describing the DNP-like theory was that it seemed so plausible and even quantitatively correct. This led many people to believe that things were basically understood and that only the multiplet effect present in the Ward and Lawler paper³ needed some small modification. It is indeed somewhat surprising that in radical reactions the DNP mechanism has never been seen to contribute, all the polarization effects being due to the stronger radical pair mechanism.

Another even earlier observation should be mentioned, namely that of electron polarization (CIDEP) by Fessenden

and Schuler⁷ in 1963. The ESR spectrum of hydrogen atoms generated by pulse radiolysis showed one hyperfine line in emission and the other in absorption. This was a single observation that did not receive much attention until it was followed up by similar findings by Smaller and co-workers.⁸

My own involvement with these polarization phenomena started immediately after the first reports of CIDNP^{1–4} in 1967. At the time I was a graduate student in the department of Professor L. J. Oosterhoff at the University of Leiden. It was a curious department, certainly by today's standards. Research projects covered an extremely broad range of subjects, from theoretical and physical chemistry to various kinds of spectroscopy, of which magnetic resonance was only one of many. It was fairly big (ca. 40 people), but Oosterhoff was there only two days per week as he also had a job at the Shell laboratory in Amsterdam. One would therefore not see much of him. In any case, in his opinion a supervisor should give his students almost absolute freedom, which suited me very well. I had started an NMR study of stable free radicals, which were observable at high concentrations in solution, because electron exchange would narrow the NMR lines. I had therefore become familiar not only with NMR but also with the properties of free radicals (hyperfine coupling, electron exchange, etc.). This gave me an excellent background to tackle the problem of the new polarization phenomena, which I took up as a bigger challenge. An experimental study of a number of diacyl peroxide decompositions⁹ showed for the first time polarization sign reversals depending on the type of product formed. Products from radical pair combination showed one sign, while those from radical scavenging reactions the opposite (this was later termed 'recombination' and 'escape' polarization). This led me to believe that radical pair interactions were somehow important, rather than processes in single free radicals as the DNP theory would suggest. After many unsuccessful attempts the answer was finally provided by a quantum mechanical description of the spin effects during birth and subsequent reactions of a radical pair.^{10,11} The surprising result was that the reaction probability of a radical pair depends to some extent on the spin state of its nuclei that are hyperfine coupled to the electron spins. This arises through the role of the hyperfine interactions in mixing singlet and triplet electronic states of a radical pair. These energetically tiny interactions are nevertheless very efficient in this mixing process, because the singlet and one of the triplet states (T_0) become degenerate shortly after formation of a radical pair in solution (i.e. the electron exchange interaction drops rapidly with distance). I had first treated the CIDEP effect in this way¹⁰ and had given an explanation of the NMR multiplet effects using cross relaxation from polarized electron states (so strong was the DNP paradigm at that time!). However I soon realized that the same mechanism could account for the nuclear spin multiplet effects as well. This also explained the sign reversals depending on product type that were called 'spin selection' (α -nuclei and up in one type of product, β -nuclei in the other). This notion that nuclear spins direct the course of a chemical reaction to some extent, was probably the most novel aspect of the new theory.

At the same time, Gerhard Closs at the University of Chicago, who died in 1992, had formulated essentially the same theoretical ideas.¹² He was looking at photochemical reactions by NMR and had noted polarization sign reversals

in reaction products depending on the initial electronic state, singlet or triplet, of the precursor molecules.^{13,14} This had led him to develop a very similar theory based on hyperfine coupling induced S–T mixing. Although his initial treatment was in terms of stochastic, relaxation-like transitions,¹² he soon adopted the fundamentally more correct description as a coherent, quantum mechanical superposition of states with an inherent oscillatory behavior. It is interesting to note that these oscillations or ‘quantum beats’ have indeed been observed experimentally.¹⁵

Once the ground rules had been laid out, the following period saw some extensions and improvements of the theory. The combined effect of hyperfine coupling and *g*-factor differences explained net polarization effects.¹⁶ A more appropriate treatment of the re-encounter probability of a diffusing radical pair^{17–19} also made the theory in quantitative agreement with experiments. A short paper²⁰ that presented simple rules for the qualitative prediction of CIDNP effects gave me great personal satisfaction. These sign rules contain all the sign reversals of the radical pair theory and apart from a few exceptions²¹ are still valid today. High-powered theoreticians came in and developed more formal versions of the theory (for a review see for instance Ref. 22; it is sad to note, however, that in this review the original papers^{10–12} are not mentioned).

In the meantime CIDNP had become a powerful tool in mechanistic organic chemistry and photochemistry. It also became clear, however, that apart from CIDNP and CIDEF the radical pair mechanism could account for various other phenomena. For instance, in optical spectroscopy it lies at the basis of ‘delayed fluorescence’²³ and ‘reaction yield detected magnetic resonance’ (RYDMR).²⁴ Also, an interesting consequence of the radical pair mechanism is the magnetic isotope effect,^{25,26} which could be used as an isotope separation tool.

In the late 1970s I became interested in the emerging field of biomolecular NMR. An application of CIDNP to proteins^{27,28} made the change of fields for me an adiabatic one. In this so-called ‘laser photo-CIDNP method’, one irradiates a protein solution containing a flavin dye in the NMR probe. Reversible electron or hydrogen atom transfer reactions cause the protons of aromatic residues (His, Tyr, and Trp) to become polarized, when these residues are surface-accessible. The obtainable information is not as complete as that of a full structural study using NOEs and coupling constants, but a virtue of the method is that it is very quick and it provides useful information, in particular on protein–ligand interaction sites.

Thus, nuclear and electron polarization and related phenomena are now firmly established in (bio)physical chemistry. I remember vividly the excitement of the early days and it has been very gratifying to be able to contribute to the development of the field. I am greatly indebted to my supervisor Professor Oosterhoff, not only for the freedom I enjoyed as a graduate student, but also for his encouragement and the stimulating environment he created. With his broad knowledge and deep insight into theoretical chemistry he was able to put some of my immature ideas into a broader perspective.

Karplus, Martin: Theory of Vicinal Coupling Constants

Martin Karplus

Harvard University, Cambridge, MA, USA

My studies of vicinal coupling constants began as a problem in theoretical chemistry. After finishing my Ph.D. (1953) at the California Institute of Technology with Linus Pauling, I went to Oxford University to work as a postdoctoral fellow with Charles Coulson. I was only 23 years old at the time and having worked hard all the way through graduate school, I was eager to have my stay in Europe provide experiences beyond science. I benefited from one of the first NSF postdoctoral fellowships. Its generous (at the time) salary of \$3000 per year permitted me to do some traveling. Consequently, I spent more time thinking about chemical problems than actually solving them. My aim was to find areas in chemistry where theory could make a useful contribution. I did not want to spend my life doing calculations whose results were of interest only to other theoretical chemists.

Reading the literature and listening to physics lectures in Oxford convinced me that magnetic resonance was an important developing area. At that time, chemical applications of nuclear magnetic resonance were just beginning. It seemed to me that nuclear magnetic resonance, in particular, was a field where theory and experiment could make mutually beneficial contributions to chemistry. The measurements could provide a means of testing the theoretical results but, more important, theory could be used to aid in interpreting the experimental results, as well as in suggesting new measurements.

As I was finishing my postdoctoral years in Oxford (1953–55) and looking for a place to begin my academic career, I decided it would be good to find an institution that had experimental programs in magnetic resonance. Fortunately, the University of Illinois had a number of openings at that time because the Department of Chemistry was undergoing a radical renovation. Several people had retired, and new people were being hired. Pauling recommended me to the University of Illinois. The department offered me a job without an interview and I accepted without visiting the department, something difficult to imagine today with the extended courtships that seem to have become an essential part of the hiring process. A major reason for going was that Charles Slichter and Herbert Gutowsky were working there. They had done some of the pioneering work in applying nuclear magnetic resonance to chemical problems. It thus seemed the perfect opportunity to combine my burgeoning interests in magnetic resonance with a position in a good department. At that time the University of Illinois offered instructorships as the starting position and the salary was \$5000 per year. As far as I can remember they offered nothing in addition, and I did not think of asking for research support before accepting the position. I felt that the University of Illinois, although a very good institution, was located in an area where I could not imagine spending more than five years. However, having had such a good time as a postdoctoral fellow visiting various parts of Europe, it was time to get to work and Urbana seemed like a place where I could work with few distractions. Up to the time I was hired,

there had been no Jews on the chemistry faculty, but with the departmental reorganization that had taken place, four Jewish instructors (Rolf Herber, Aron Kupperman, Robert Ruben, and I) were hired at the same time. This group, plus other young scientists on the faculty such as Lynn Belford, E. J. Corey, and Doug Applequist, led to a very active interactive and congenial atmosphere during my stay.

On arriving in Urbana, I decided to focus part of my research on theoretical methods for relating nuclear magnetic resonance parameters to the electronic structure of molecules. The first problem I examined was concerned with proton–proton coupling constants which were known to be dominated by the Fermi contact interaction. What made coupling constants of particular interest was that for nonbonded protons, the existence of a nonzero value indicated that there was an interaction beyond that expected from localized bonds. In the valence bond framework, which I used in part because of my training with Pauling, the nonzero coupling constant provides a direct measure of the deviation from the perfect pairing approximation.

D. H. Anderson, a graduate student working with Gutowsky, treated the proton–proton coupling in methane with a theoretical model that I had developed and obtained results in excellent agreement with experiment.^{1,2} The calculated value was 12.5 c/s versus the measured value of 12.4 ± 0.6 c/s; as is usual in most calculations on many-electron systems, the theoretical result had no error bars. Encouraged by this success, we went on to extend the coupling constant theory to other problems. Examples are the calculation of the HCH' angular dependence of the proton–proton coupling in methylene groups³ and the interpretation of the directly bonded coupling between a heavy atom (¹³C, ¹⁵N) and a proton in terms of the hybridization and ionic character of the bond involved.⁴

Some time later the apparent 'excellent' agreement of the original calculation for methane was shown to be an illusion. A number of papers appeared in 1961 that demonstrated experimentally that the geminal and vicinal proton coupling constants had opposite signs, whereas theory predicted them to have the same sign. I was very upset by this development. It is never pleasant publishing something that is wrong and it is particularly unpleasant to do so at the beginning of one's career. I went back to reexamine the theory and concluded that it was the geminal coupling constant which was wrong because the final result depended on several terms with opposite signs that nearly canceled.⁵ Further, I suggested an experiment⁵ which could be used to measure the sign of the coupling constant so as to test my conclusion. Subsequent measurements confirmed the analysis, which indicated that vicinal coupling constants were positive and that, therefore, geminal coupling constants were negative.

There are two reasons for describing the problem with the geminal coupling calculation, even though I am probably one of the few people who still remembers it. First, the vicinal coupling theory, which is the reason for this chapter, would probably not have been developed if I had not believed that the geminal coupling constant result was so good. Second, like many a young faculty member, I was concerned about making some 'distance' between Gutowsky and myself. He was known worldwide for his research in NMR. I wanted to show that the calculations were 'my' work, though there is no question that I profited greatly from discussions with him and from access to

his students like Dave Anderson and Tom Farrar. After some discussion, we agreed that we would divide up the geminal and vicinal coupling work. Gutowsky would appear on papers describing one of the two and not on those concerned with the other. For various reasons, including that I had done the vicinal coupling calculation by myself, I picked that. It was a lucky choice.

As in the case of methane, I used valence bond theory to calculate the value of the vicinal proton–proton coupling constant in the $\text{HCC}'\text{H}'$ fragment as a function of the dihedral angle. The formal theory of coupling constants^{2,3} and other second-order properties⁶ had been developed already so that the problem was one of its application. Because the proton–proton interaction corresponds to a second-order perturbation theory contribution, it requires evaluation of a sum over excited states. This was difficult to do accurately at the time because of the slow convergence of the sum. To avoid the excited state summation problem, the so-called ‘average energy approximation’ was introduced. It leads to the following expression for the vicinal coupling constant $J(\text{H},\text{H}')$:

$$J(\text{H},\text{H}')(\text{c/s}) = -\frac{1.210 \times 10^{-45}}{\Delta E(\text{eV})} \left\langle \psi \left| \sum_{j,k} \delta(\mathbf{r}_{j\text{H}}) \delta(\mathbf{r}_{k\text{H}'}) S_j \cdot S_k \right| \psi \right\rangle \quad (1)$$

in a standard notation. The average energy approximation could introduce problems because the coupling constant involves two different perturbations.⁷ However, there was no alternative and it seemed necessary to apply an approximation that might not be fully justified so as to be able to treat systems of interest with the methods and resources that were available. A more recent case of this type is the application of molecular dynamics simulation methods to proteins. They were used first when the potential functions were not accurate enough and the computers permitted only simulations that were too short. In spite of this, the original work⁸ was instrumental in introducing a dynamic view of proteins. Since then, the utility of such simulations has been demonstrated repeatedly and many people are now using them with better potentials and longer simulations to study a wide range of problems.^{9,10}

Although the $\text{HCC}'\text{H}'$ fragment is a relatively simple system consisting of six electrons with the neglect of inner shells, and can be described approximately by including only five covalent valence bond structures, the calculations for a series of dihedral angles were sufficiently time consuming that it seemed worthwhile to develop a computer program. This was not as simple in 1958 as it would be now. Fortunately, the University of Illinois had built the ILLIAC, a large scale computer at that time. If I remember correctly, it had a 1000 words of memory, which was sufficient for my simple program. The actual program was written by making little holes in a paper tape. If you made a mistake, you filled in the incorrect holes with nail polish so that you could continue the program. The output appeared on spools of paper, some of which I still have today. Probably the most important aspect of having a program was that once it was known to be correct, a large number of calculations could be done without having to worry about arithmetic mistakes.

Just as I finished the work on vicinal coupling constants,¹¹ I heard a lecture by R. V. Lemieux on the conformations

of acetylated sugars.^{12,13} I do not remember why I went to the talk because it was on organic chemistry. Lemieux reported results for vicinal coupling constants and noted that there appeared to be a dihedral angle dependence, although the details of the behavior were not clear. However, it was evident that these experimental results confirmed the theory, even before it was published.

Having completed the vicinal coupling constant theory and found that it yielded results in reasonable agreement with experiment, my feeling was that the project was done although I continued to explore the insights that such an approach could give concerning the electronic structure of molecules.^{6,14} I soon became interested in other problems, including the theory of chemical reactions.^{15,16} As in magnetic resonance, my interest in this field was stimulated by the development of new experimental techniques. Most important was the introduction of crossed molecular beams for the study of the collisional aspects of chemical reactions.¹⁷

E. J. Corey, who was at that time an assistant professor at Illinois and later became a colleague at Harvard, was one of the people with whom I had dinner on a fairly regular basis at the Tea Garden, a passable restaurant in Champaign-Urbana. We often discussed recent work that we thought might be of mutual interest and one day I described the studies that I had made of vicinal coupling constants. Corey immediately recognized the possibility of using the results for structure determination and shortly published what is probably the first application in organic chemistry.¹⁸ Shortly after, the theory appeared in a comprehensive review of the use of nuclear magnetic resonance in organic structure determinations.¹⁹ Someone introduced the name ‘Karplus equation’ for the relationship I had developed—a mixed blessing which was to haunt me for many years. Many people attempted to apply the equation to determine dihedral angles in organic structures and, of course, since it was a qualitative relationship, found deviations of the measured coupling from the predicted dihedral angle dependence for known structures. All of this came to a head when several papers were published²⁰ pointing out that the equation was not as accurate as many chemists seemed to have assumed it to be.

Most people who use the ‘Karplus equation’ appear not to have read the original paper¹¹ and so did not know the limitations of the theory cited there. They assumed that because the equation had been used to estimate vicinal dihedral angles, the theory said that the coupling constant depends *only* on the dihedral angle. By 1963, I had learned that important organic chemists write and read only Communications to the *Journal of the American Chemical Society* and so I decided to publish such a Communication,²¹ in which I described various factors, other than the dihedral angle, that are expected to affect the value of the vicinal coupling constant; they include the electronegativity of substituents, the valence angles of the protons (HCC' and $\text{CC}'\text{H}'$) and bond lengths.²¹ The main point of the paper was not to provide a more accurate equation but rather to make clear that caution had to be used in applying the equation to structural problems. My closing sentence, which has often been quoted, was the following: ‘Certainly with our present knowledge, the person who attempts to estimate dihedral angles to an accuracy of one or two degrees does so at his own peril’.

In spite of this caution, the use of the equation has continued and the original paper¹¹ is one of the *Current Contents* ‘Most

Cited Papers in Chemistry'. In addition, there have been many empirical 'extensions' of the equation; perhaps the most complex published form is given in Ref. 22, where a 12-term expression is introduced. Equations have been developed also for vicinal coupling constants involving a variety of nuclei²³ (e.g. $^{13}\text{C}-\text{CC}-\text{H}$, $^{15}\text{N}-\text{CC}-\text{H}$) and they have been applied in areas ranging from inorganic through organic to biochemistry. One of the more recent uses is as part of the data employed in the structure determination of proteins by NMR.^{24,25}

The vicinal coupling constant model, which I developed to understand deviations from perfect pairing, has been much more useful than I would have guessed (obviously I am very pleased with this) and refinements based mainly on empirical fits have been found helpful in obtaining improved results. In many ways my feeling about the uses and refinements of the 'Karplus equation' is that of a proud father. I am very pleased to see all the nice things that the equation can do, but it is clear that it has grown up and now is living its own life.

Martin Karplus. b 1930. B.S. 1950 (Harvard), Ph.D. (California Institute of Technology, supervisor Linus Pauling). Postdoctoral fellow, Oxford University, 1953–55 (with Charles Coulson); instructor, assistant professor, associate professor, University of Illinois, 1955–60; professor, Columbia University, 1960–66; professor, Harvard University, 1966–present; Theodore William Richards Professor of Chemistry, Harvard University, 1979–present; Professeur Associé, Université de Paris-Sud, 1972–73, 1980–81; Professeur, Université de Paris VII, 1974–75; Professeur, Collège de France, Paris, 1980–81, 1987–88; Professeur Associé, Université Louis Pasteur, Strasbourg, 1992, 1994–95; Professeur Conventionné, Université Louis Pasteur, Strasbourg, 1995–present. Approx. 500 publications. Research interests: theoretical chemistry, including the electronic interpretation of NMR and ESR spectra of molecules, the development of techniques for the evaluation of molecular properties, and the formulation of detailed models for chemical reactions. Recent work is concerned with molecules that play an important role in living systems.

Keller, Tony: The Development of the First Multinuclear Fourier NMR Spectrometers

Tony Keller

Bruker Analytische Messtechnik, Rheinstetten, Germany

In the late 1960s heteronuclear NMR spectroscopy began to stimulate the interest of many spectroscopists. Our goal at Bruker was to design spectrometers that could meet the many challenges this application posed. Heteronuclear field/frequency lock (first ^1H , then ^{19}F and ^2H) and time averaging with a multifrequency CW spectrometer had been developed, but a big problem remained—sensitivity. Long nights of data accumulation with a ‘CAT’ (computer for accumulating and time-averaging analog signals) were needed for ^{13}C NMR of very concentrated samples, and you were lucky just to see peaks emerging out of the ‘grass’. Some exotic possibilities for improving sensitivity, such as the simultaneous use of a multitude of transmitter and detector frequency channels, were contemplated but these possibilities could not be realized with the technology of the day. It was like experiencing a beautiful sunrise when I first heard about the Fourier spectroscopy results obtained by Anderson and Ernst. However, many pessimists considered the odds to be slim that FT methods would ever become practical for several reasons: limited applications, excessively long T_1 relaxation times were expected (e.g. for ^{13}C), complexity and expense of the method with only minor benefits expected for day-to-day spectroscopy.

For me, it was clear that I just had to give it a try. It is always challenging to find out if the signs of the time are right. It was obvious that the ‘lorry approach’ of Ernst and Anderson (data transfer to a mainframe computer via truckloads of punchcards) would not be very popular with our customers, whose acceptance of any new method is our measure of success. However, our supplier of data acquisition processors, Fabritek, revealed that they could combine their averaging system with a PDP-8 computer.

Our CW multinuclear spectrometer was already a success and it needed only minor modifications. We had just finished developing a transmitter/receiver time-sharing system in order to get rid of drifting baselines during long accumulations with the traditional modulation scheme. This pulsed mode for frequency sweep spectroscopy utilized a wideband receiver system that was appropriate for Fourier techniques. At the time, while living in the United States, I was also working with a group of engineers in Germany to develop a new broad-band proton decoupler. At once, our design goal became a combined broadband ^1H and multinuclear power transmitter.

Many trips across the Atlantic were necessary until in the summer of 1969 two transmitters arrived in Elmsford, NY, Bruker’s US headquarters in those years. At the same time a brand-new PDP-8/Fabritek 1074 combination started to work. The first experiments with ^1H detection were only marginally successful; the ^{19}F lock was not very stable under

the influence of the strong ^1H pulses that were being applied to our high-resolution instruments for the first time. Therefore, I decided to have a go at the really tough challenge—broadband ^1H -decoupled ^{13}C FT NMR—giving me the chance to check out our new BB decoupler at the same time. I had already decided that noise modulation would not provide efficient decoupling, so I developed a 180° phase modulation scheme with an adjustable sawtooth ramp for the modulation frequency. In fact, this BB method, especially in its later optimized digital form, proved to be the most efficient scheme available until composite pulse methods were introduced in the 1980s. Anyway, back in 1969 the time for serious NMR measurements was usually just after midnight, and when the first ^{13}C test started the screen was filled immediately with what looked like hideous rf interference or cross talk. But wait a moment, *this looks like a free induction decay and it’s growing!* Now the time for strong nerves had come: Fourier transformation of a 1k spectrum took 5–10 minutes. Then, for the first time, I was looking at a BB-decoupled ^{13}C spectrum with $\text{S/N} > 100$.

A few days later, the Anaheim conference on ^{13}C NMR spectroscopy was to be held, and, of course, I wanted to show the first spectra made with my FT system. So I frantically performed FT NMR spectroscopy day and night on every substance I could get my hands on. It was just so beautiful to be able to measure NMR signals that had never been seen before. I was so excited about turning out spectral ‘masterpieces’ one after the other that I nearly missed the plane to Los Angeles. One of the first to see my treasures was Tom Farrar. He was so excited himself that he gave me five minutes of his lecture time to present my data (Thanks, Tom!). When the most famous ^{13}C spectroscopist of the CW era stepped into our hospitality suite, he pondered my decoupled ^{13}C spectra hanging on the wall and asked, ‘Do you also have ^{13}C data?’ It took me a long time to convince him that, in fact, he had ^{13}C spectra before his incredulous eyes (Figure 1).

In the following weeks I learned the basics of FT NMR spectroscopy and ran the first FT spectra of ^{31}P , ^{29}Si , ^{119}Sn , ^{11}B , and several other nuclei. Of course, I was confronted with a number of new problems that required new solutions in order to make the technique as easy to use as CW spectroscopy. Even ^1H NMR was increasingly being done with FT methods (only the ‘oldtimers’ can appreciate how much we missed those beautiful wiggle beats), and I finally found a solution to one of the burning issues for proton FT NMR: *homonuclear* decoupling. All the traditional ways of generating an irradiation sideband failed. As always, when

Figure 1 FID and spectrum from one of the first ^{13}C FT NMR experiments. As one can clearly see the spectral paper was the kind we used for ^{13}C CW spectroscopy

Figure 2 ^{13}C FT NMR works, and children have to fetch their goodnight kiss at the spectrometer

NMR knowhow did not help, I had to rely on my electronics background and radar experience, which told me that I should

generate the sideband with a fast, repeating pulse (long before DANTE entered the scene). The NMR specialists with whom I consulted were very skeptical of the new idea, which required the synchronization of the decoupler pulse train with the data acquisition dwell time. In the end, pulsed homonuclear decoupling was indeed successful. After a relatively short development time, we proudly exhibited the first FT-only NMR spectrometer at the Pittsburgh conference in 1972.

Tony W. Keller. *b* 1937. Employed with Trüb Täuber AG, Switzerland, NMR division as a service engineer, 1960. Transfer of NMR activities of Trüb Täuber to Spectrospin AG, Switzerland, later appointed as one of the directors, 1965. Establishment of Bruker Group representation in the USA, development of first commercial FT-NMR system, 1969. Employed with Bruker Physik AG being responsible for the NMR division, 1973. Appointed Managing Director, Bruker Analytische Messtechnik GmbH, 1979. Honorary doctorate of the Technical University, Berlin for achievements in the development of NMR, 1989. Author and co-author of numerous patents.

Kessler, Horst: Dynamics by NMR

Horst Kessler

Technical University München, Garching, Germany

In the early 1960s NMR spectroscopy became a popular method for elucidating the structures of organic compounds. Working on my thesis in Tübingen under the guidance of Eugen Müller, I reacted diazomethane catalytically with aromatic compounds yielding norcaradienes or cycloheptatrienes. NMR was ideally suited for identifying the structure of the reaction products. I was soon collecting NMR spectra for the whole group using our 56.4 MHz Varian spectrometer, later with an A-60. The observation of broad lines in several spectra fascinated me and I began to study exchange processes. At that time only a few of these processes were known. Exchange rates which were too fast to allow the isolation of isomers were not accessible. It was a golden age for organic chemists to look at such processes and study substituent effects to elucidate the details of internal mobility.

Substituent effects were used to increase barriers to allow separation, e.g. the first *N*-monosubstituted amide rotamers could be separated in 2,4,6-*tert*-butylacetanilide and the equilibration observed by NMR.¹ Substituent effects have also been used to facilitate rotations about carbon–carbon double bonds via biradical or push-pull stabilized polar transition states. We found several new examples of hindered rotation, e.g. about single bonds and partial double bonds.² A particular interest at that time was to prove the mechanism of the *syn*–*anti* isomerization of imines and related compounds. Substituent effects of X, Y, Z strongly favored the inversion mechanism over single-bond rotation. In particular, stereochemical arguments relating to guanidines with prochiral groups in the *ortho* position provided strong evidence for the preference of the inversion pathway (Scheme 1).³ We later investigated barriers for ion recombination to covalent species.⁴ Free enthalpies of activation of 10 kcal mol^{−1}, for the dissociation and recombination between triphenylchloromethane and the triphenylmethyl cation/chloride anion, for example, were a big surprise to us as solvation effects were ignored at that time.

When the field of DNMR (dynamic NMR) had been established, we turned to peptide conformations which appeared to be of biological relevance. We soon realized that the flexibility of these substances limits and averages the conformational data that can be obtained and hence conformational restrictions provided by cyclization must be utilized.⁵ Hence, small cyclic peptides were our primary target in synthesis and for conformational investigation. The advantage of constraints via cyclic modifications of linear bioactive peptides is that higher activity and receptor selectivity can be obtained whereby the bioactive conformation of the recognized peptide sequence can be locked in.⁵ Our speculation that small recognition areas should be found in the loop regions of proteins was established in several cases and small cyclic peptides turned out to be the best way for proving the spatial orientation of pharmacophors in peptides (see, for example, for RGD-containing cyclopeptides for the inhibition of cell–cell adhesion).⁶ One

Scheme 1 Inversion and rotation pathways in guanidines

of our patients turned out to be a potent and selective inhibitor for angiogenesis in tumors and may lead to a new concept of tumor therapy.¹⁶ From the viewpoint of an NMR spectroscopist, restriction may force the molecule into a preferred conformation which can be determined experimentally. We also became aware that the preferred conformation does not necessarily coincide with the conformation in the crystal⁷ or at the receptor. Hence as many restrictions as possible have to be incorporated into peptides to allow conclusions about the bioactive conformation.

Sensitivity to environmental effects and the lack of sufficient experimental data led us to the ‘all-atom approach’, whereby ¹⁵N and ¹³C NMR parameters, in addition to those of ¹H, are included for structure determination.⁸ To avoid circular conclusions, constitutional assignments have to be separated, if possible, from spatial structure determinations. As a consequence we prefer heteronuclear long-range couplings over NOEs for the sequential assignments of a peptide. Restrained molecular dynamics, and later distance geometry calculations, were used to derive an experimentally based structure model compatible with our experiments. This need not be the single ‘true’ structure, if such a thing exists at all. However, many other conformations can be excluded by this procedure.

If sufficient data are available, internal inconsistencies between the experimental NMR parameters can be identified which often indicate conformational flexibility. Rapid conformational equilibria may be detected by analyzing *J* coupling constants⁹ or via NOEs.¹⁰ Recently *J* coupling constants have also been used as restraints in distance geometry and ensemble calculations.¹¹

The most important help for our approach came from the development of multidimensional NMR spectroscopy. We came into this field at the end of the 1970s. The exchange of co-workers with Ray Freeman (Regina Schuck, Hartmut Oschkinat) and Richard Ernst (Herbert Kogler, Christian Griesinger) greatly sped up our ability to use the new methodology. Within a short time we were able to develop or modify the pulse sequences needed for the work mentioned above. To name a few: improved heteronuclear correlations (COLOC as constant time hetero COSY¹²), concatenation of π pulses in H,H,C-relayed COSY,¹³ nonsynchronous π pulses for scaling down *J* coupling in a fixed delay,¹⁴ 1D analog

of 2D experiments by selective Gaussian or half-Gaussian excitation,¹⁵ improvements of some 3D heteronuclear triple resonance experiments, and some methods for extracting coupling constants from multidimensional spectra. In 1986, when Hartmut Oschkinat and Christian Griesinger worked on the 'soft analog' of the relay spectrum, we performed a 2D analog by incrementing the relay–delay yielding 'half a 3D spectrum'¹⁵ which we called the 'one-and-a-half-D' in our lab slang. Later on when Christian went to Richard Ernst, he developed 3D spectroscopy, still in collaboration with Hartmut, who was working with Geoffrey Bodenhausen in Lausanne at that time. What began as playing with ideas turned out to be an important extension of 2D into higher dimensions.

In summary, we have always been interested in the structure and dynamics of molecules as a means of understanding their physicochemical and biological properties. The development of NMR during the last 30 years has sharpened our perception of the structural variety and interconversions between the large number of conformations on different timescales. In this respect, NMR has contributed significantly to the modern view of dynamic structures and their relevance for understanding molecular behavior and molecular recognition.

Khetrapal, C. L.: Development of NMR of Oriented Systems

C. L. Khetrapal

Indian Institute of Science, Bangalore, India

The utility of anisotropic NMR parameters, particularly the direct dipolar and quadrupolar couplings, in the precise determination of molecular structure has been well recognized since the early days of NMR. In practice, such interactions have been observed in the solid state and utilized for the study of the structure of crystals since the 1950s. However, the presence of intermolecular interactions in the solid state drastically limits the precision of the derived information. Hence, a well defined goal of NMR spectroscopists was to discover a technique whereby such interactions could be observed and measured from the line-frequency separations rather than the linewidths. Several ideas such as the use of an electric field, the adsorption of molecules in polymers with subsequent stretching, and embedding the molecules in zeolite crystal channels were tried initially, but not much success was achieved until 1963 when Saupe and Englert for the first time prescribed the use of liquid crystals as solvents for such a purpose. This gave birth to the new field of NMR spectroscopy of oriented molecules. Since then the field has developed rapidly, particularly for the determination of relative internuclear distances and bond angles. Though the potentials and promises of the technique become apparent from the principles underlying the phenomena, the actual developments have several interesting stories associated with them.

Soon after their discovery, both Saupe and Englert left Freiburg, Germany, where the discovery was made. Saupe moved to the Liquid Crystal Institute, Kent, OH, USA while Englert joined a pharmaceutical company in Basel, Switzerland. The physical separation of the two was a blessing in disguise for the development of the field. Saupe continued his main research work in the area of liquid crystals *per se* with some interest in the field of NMR of oriented molecules, particularly in the study of small molecules with high symmetry. Englert in Basel, being in a pharmaceutical company, could not devote a proper share of his time to nursing his own baby but was alert to the potential and utility of the discovery. He, therefore, used to have frequent discussions with Peter Diehl from the Physics Department of the University of Basel. Diehl became keenly interested in exploring and developing this area as a routine method for the study of molecular geometries in the liquid phase. Around the same time, an active group emerged at the Bell Telephone Laboratories headed by Meiboom and Snyder and in Columbia University under the supervision of Dailey with Yannoni as a collaborator. Another active group emerged in England with Buckingham as the leader and Burnell and de Lange as younger colleagues who joined subsequently; they mainly concentrated on the use of the method for the determination of chemical shielding anisotropy. The Bell Lab group, on the other hand, provided the motional constants approach for describing molecular order. The main interest

of the group at Columbia was towards the use of the method for the study of chemical shift anisotropies and the structure of highly symmetric molecules such as cyclobutadiene iron tricarbonyl.

It was at this stage in 1967 that I joined Diehl's group in Basel. Though we realized the bright future of the subject, we were slightly discouraged by the warnings of others already in the field. In addition, overall knowledge on the subject was close to nil at that time. The goal, however, was clear. In order to open up the field to practical NMR scientists, the group in Basel studied the dependence of the spectra on the temperature, concentration, and spinning speed of the samples. The use of direct and moment methods for the analysis of such spectra was also developed. Extension to molecules with lower symmetry and to larger molecules was attempted. Studies on intramolecular motions, isotopic effects on molecular structure and order, and quadrupole coupling constants were undertaken. The existence of deceptively simple spectra under various conditions was pointed out. The use of electric fields to rotate the liquid crystal director in the magnetic field was demonstrated. It became obvious during 1968–69 that the spectra of molecules oriented in nematic liquid crystalline phases were, in general, strongly coupled unless heteronuclei were involved. This apparently restricted the utility of the method for the determination of molecular structure and function of systems with more than about six chemically different interacting nuclei. Furthermore, the work on oriented systems utilized nematic phases at high temperatures. At this stage, I left Basel and thus the group bifurcated with the creation of another group at the Tata Institute of Fundamental Research, Bombay, India.

Lytotropic liquid crystals formed by C_8 or C_{10} alkyl sulfates with the corresponding alcohols, sodium sulfate, and water were discovered as orienting media between 10–75°C by Black and others in Cincinnati around 1967–68. The advantage of such media was that they were usable at ambient temperatures and the spectra in general were 'weakly' coupled, and hence amenable to simpler analysis procedures. Subsequently many new lyotropic liquid crystals were discovered and extensively utilized by Reeves and Tracey in Canada, Long and Goldstein in the US and our group in Bombay.

Our group has been involved in the extension of the method to larger spin systems with lower symmetries and organometallic compounds. On the other hand, the Basel group has concentrated mainly on the development of automatic analysis procedures and iterative computer programs for the interpretation of the derived dipolar couplings in terms of molecular structure.

The decade starting in 1970 was the golden age for developments in the field of oriented molecules. The discovery of room temperature thermotropic nematic liquid crystals during this period has been significant in advancing this field. In addition, the use of lyotropic liquid crystals for the study of the dynamic properties of membranes and model systems was proposed by Charvolin in France and Seelig in Basel. Both techniques have been extensively utilized by various active groups such as those of Smith and Bloom in Canada.

The use of specifically deuterated materials followed by proton decoupling as a technique for the simplification of complicated proton spectra proposed by Meiboom, Snyder, and Luz in 1971–73 was a landmark. The use of perdeuterated

systems as an aid to the analysis of complicated proton spectra is a corollary of the above and has been extensively employed. At this stage, Luz moved over to Israel and established a group there. This group has been most active in developments relating to spectral simplifications, dynamical studies, and smectic and discotic liquid crystals. Simultaneously, I visited Kent for about a year and collaborated with Saupe in solving various structural and conformational problems of chemical interest.

Subsequently, the Bombay group in India shifted to Bangalore to establish an active group there. Efforts were still concentrated towards developing techniques for spectral simplifications, since none of the above-described methods could provide a routine technique for such a purpose. The pioneering work of Alex Pines and his colleagues in Berkeley in the use of multiple quantum and zero field spectroscopies in the late 1970s and early 1980s were steps forward in this direction. Various two-dimensional NMR techniques have been proposed and extensively exploited for such purposes by the groups of Emsley in Southampton, myself and Anil Kumar in Bangalore, and Fung in Oklahoma. Emsley and his offshoots in Italy became active in the interpretation of ultracomplexed spectra. They claim that they should be able to analyze the spectrum of any molecule however complex it may be.

In the meantime, magic angle spinning methods became available commercially. I proposed in 1979–80 that the use of near magic angle sample spinning could be employed for the simplification of the spectra of oriented molecules. This was achieved experimentally by Grant and his colleagues around 1981.

At this stage, Ted Becker of the National Institutes of Health, USA became deeply interested in exploring the utility of the technique for biologically important problems. He invited me to collaborate with him in this area. This resulted in many significant developments in the field of NMR of oriented biologically important molecules, such as substituted imidazoles, model peptide systems, and substituted uracils, etc.

Another breakthrough in the technique towards new applications took place in Bangalore in 1981–82 where the use of liquid crystals of opposite diamagnetic anisotropies was

proposed. In view of the utility of such experiments, an independent chapter on this topic is included in this Encyclopedia (*Liquid Crystals: Mixed Magnetic Susceptibility Solvents*).

Other active groups which emerged in the 1980s are those of Bucci, Veracini, Longeri, and Chidichimo in Italy. They have specialized in maximum entropy approaches and flexible molecules. During the same period an active group under the supervision of Jokisaari developed in Oulu in Finland in collaboration with Diehl in Basel. This group specialized in the study of structural and conformational problems of various types, such as those in spherical molecules, rare gases, and the use of mixed liquid crystals of opposite diamagnetic anisotropies.

In 1989, Diehl visited Bangalore, and we initiated work on the study of metal-ion ligand interactions in thermotropic liquid crystals and discovered induced smectic phases in mixtures of nematics using NMR.

In the current decade, the state-correlated two-dimensional NMR experiments proposed by Akasaka and his team in Japan appear to be potentially valuable for spectral analysis purposes.

The use of an electric field for orienting the molecules has been developed by MacLean and his colleagues in the Netherlands, essentially in the 1980s. The use of a magnetic field for similar purposes is a future hope when spectrometers operating at ultrahigh magnetic fields become available.

Biographical Sketch

C. L. Khetrapal. *b* 1937. M.Sc., 1959, Allahabad, Ph.D., 1965, Bombay. Introduced to NMR by S. S. Dharmatti. Worked at Tata Institute of Fundamental Research, Bombay, 1959–73 in various positions, the last one being reader; Raman Research Institute, Bangalore, 1973–84, as Associate Professor and Indian Institute of Science, Bangalore, 1984–present, as Professor and Head, Sophisticated Instruments Facility. Nearly 200 publications and several reviews, books, and monographs. Research interests include NMR of oriented systems with emphasis on molecular structure and function, developments of novel techniques, and applications of NMR imaging and in vivo spectroscopy to problems of agricultural interest.

Klein, Melvin P.: Recollections of 40 Years of Magnetic Resonance at Berkeley

Melvin P. Klein

Lawrence Berkeley Laboratory, University of California, Berkeley, CA, USA

My introduction to magnetic resonance derived from the great activity in Berkeley during the early 1950s because of the presence of the experimentalists Erwin Hahn, Carson Jeffries, Walter Knight, and Arthur Kip, all of whom were prodded on by the theorist Charles Kittel. George Feher was also a graduate student and it was in kibitzing his experiments on EPR in the alkali metals at 100–300 MHz that I first saw a resonance curve traced out.

The need for a good magnetic field measurement obliged me to get some hands-on experience with magnetic resonance and also to become acquainted with the spins and moments of many nuclides other than protons. This led subsequently to the measurements of the abundance ratio of the lithium isotopes in collaboration with B. E. Holder.¹ Measurement of the chemical shifts of nitrogen followed.²

One of our colleagues, the late G. E. Barton, Jr., was performing mass spectroscopy with data acquisition by ion counting into a pulse height analyzer. The nuclear physics community had developed these devices to measure the energy-intensity distribution of γ -rays. In these devices an analog-to-digital converter measures the height of the light pulse produced by a scintillator–photomultiplier and converts it into an address, adding one count to the register corresponding to that address. Barton's mass spectrometer was arranged to map the magnetic field intensity, corresponding to a given e/m ratio, onto an address in the analyzer and to add a count for each ion reaching the detector. We had often discussed that such a scheme would be very useful for our NMR and EPR measurements, if we could find some clever way of digitizing the outputs of these spectrometers.

These feelings were reinforced during a sabbatical at Bell Labs where I often passed by a Mössbauer apparatus dutifully accumulating ^{57}Fe counts as a function of the velocity of the sample. Shortly after my return to California we learned of the newly developed voltage-to-frequency converter. Barton and I immediately acquired one of these devices, connected it to a borrowed pulse height analyzer, and in a relatively short time demonstrated signal averaging. Our most impressive achievement at that time was to acquire the signal of deuterium in natural abundance in absorption, without a lock-in.³

It is surely not my intention to review all of our activities but a few areas do stand out in my memory.

As sensitivity and signal-to-noise ratio seem to have been a preoccupation, I fondly recall the measurement of the NMR in an excited state of a short-lived radionuclide. In this experiment the technique of perturbed angular correlation was employed. A parent nucleus decays by two successive γ -rays with a common intermediate state. The angular correlation between the γ -rays was measured and then the effects

of a radiofrequency field on this time correlation function determined. We were able to detect essentially the NQR of this state with some 200 000 counts.⁴

The excitement of the Fourier transform spectroscopy introduced by Ernst and Anderson did not take long to cross San Francisco Bay. We acquired FIDs in a primitive signal averager which was in turn connected to a paper tape punch. Data were carried from the campus to Lawrence Berkeley Laboratory, where the computers we used were located together with some program elements that Richard generously supplied. Surely, the FTs worked. One day John Waugh called and suggested that we do T_1 measurements by FT methods for complex spectra. That, too, worked nicely.⁵ The technical endeavors of John Despotakis who built the first computer based (PDP-8) data acquisition system for performing FT NMR are warmly remembered.

It was during this period that Himan Sternlicht, then in the Berkeley Chemistry Department, became convinced that ^{13}C NMR would become an enormously useful tool. He began his work using indirectly detected resonance, but knew exactly the benefits to be derived from pursuing the Fourier methods. He began such work in Berkeley but unfortunately left the field.⁶ His prescience is amply justified by the impact that ^{13}C spectroscopy has had in the chemical and biological sciences.

Another Berkeley colleague, J. B. Neilands, had isolated a series of small natural iron chelators which he called siderophores, principally the ferrichromes. These compounds with a molecular weight of about 1 kD were of broad interest. The EPR signals of the high spin Fe^{3+} were among the first of the well-studied $g = 4.3$ species.⁷ The Mössbauer spectra of these molecules were the first to exhibit and have relaxation effects explained.⁸ The Fe^{3+} ion could be replaced by Al^{3+} and Ga^{3+} . Thus they became amenable for study by high-resolution NMR in our then state-of-the-art 220 MHz spectrometer. Our student Miguel Llinas carried structural interpretations far beyond anything we believed possible at the outset.⁹ It was on these molecules that the first FT double resonance experiments were performed on ^{15}N -substituted molecules.¹⁰ Had we looked and thought more carefully about these spectra, we might have stumbled onto 2D heteronuclear NMR before it was first suggested by Jeener.¹¹

Our activities in proton and ^{31}P NMR in model and true membranes with Rick Horwitz, Danny Michaelson, and Sue Kohler¹² were followed by Kohler's measurements on single crystals of model phosphorus-bearing compounds, the aim of which was to provide the full shift-tensor information.¹³ The motionally-averaged spectra could then be used to infer correlation times of the motion of phospholipids in the membranes. Much later, ^{31}P data became important for in vivo spectroscopy and Sun Un was able to use MAS spectra to derive information on the forms of ATP in tissue.¹⁴

The early endeavors by two students, Greg Karczmar and Alan Koretsky, into in vivo NMR spectroscopy have led them to very productive careers.¹⁵ The excellent experiments and interpretations on ammonium ions in the solid phase by Tom Pratum also stand out.¹⁶

Finally, our introduction of ^3H NMR as a highly useful addition to the toolbox of biological NMR is recalled with pleasure. This activity was inspired by my colleague R. M. Lemmon who had begun the synthesis of tritiated compounds for the purposes of tracing the pathways of molecules in the photosynthetic conversion of CO_2 to carbohydrates under

Melvin Calvin's urging. It was possible to know the specific activity of the labeled compound, but the distribution of the label in the compound could only be guessed from the synthetic routes. As the chemical shifts of ^3H and ^1H are identical on a ppm scale, aside from some very subtle isotope effects, a tritium NMR (TMR) spectrum would be directly interpretable. The National Tritium Labeling Facility at LBL was subsequently established and uses TMR in a routine fashion.¹⁷

I have enjoyed and benefited enormously from the interactions with colleagues in the magnetic resonance communities. Most especially, I acknowledge the contributions and friendship of the students, postdoctoral fellows, sabbatical visitors and other colleagues with whom I have had the privilege of working. They are: W. A. Anderson, W. E. Blumberg, R. D. Britt, A. Bothner-By, M. Calvin, P. J. Carson, S. I. Chan, V. J. DeRose, J. Despotakis, S. L. Dexheimer, J. D. Ellett, R. E. Ernst, K. E. Falk, R. Freeman, D. M. Grant, M. Guéron, E. L. Hahn, J. A. Happe, B. E. Holder, W. J. Horsley, A. F. Horowitz, J. S. Hyde, C. D. Jeffries, G. S. Karczmar, S. J. Kohler, A. P. Koretsky, J. C. Lagarias, M. Llinas, W. Lubitz, J. L. Markley, A. E. McDermott, E. Matthias, D. M. Michaelson, W. B. Mims, K. Möbius, C. M. Oshiro, M. E. Packard, D. E. Phelps, A. Pines, A. M. Portis, T. K. Pratum, I. Salmeen, J. C. Schoolery, W. C. Shih, D. A. Shirley, G. E. Smith, D. Stehlik, H. Sternlicht, D. M. Teaney, M. Tomkeiwicz, R. L. Vold, C. G. Wade, R. L. Ward, J. S. Waugh, M. W. Weiner, D. E. Wemmer, H. H. Wickman, P. G. Williams, D. M. Wilson, K. Wüthrich, and V. K. Yachandra.

Klinowski, Jacek: Historical Sketch: Molecular Sieves

Jacek Klinowski

University of Cambridge, Cambridge, UK

The development of magic angle spinning (MAS) NMR by Andrew and his colleagues^{1,2} at the University College of North Wales, Bangor, and by Lowe³ at Washington University, St. Louis, initiated a new era in the structural study of solids. The technique has greatly enhanced our knowledge of a wide range of materials used in chemical, physical, biological, and earth sciences, and in the technology of glass and ceramics. The term 'magic angle spinning' was coined by Gorter in 1960 when he heard Andrew's results presented at the AMPERE congress in Pisa.

It took nearly 20 years for MAS to become a routine tool for structural investigation. The reasons were the difficulty of spinning the sample at the very high speeds required and the insufficiently high magnetic fields. However, the introduction of Fourier transform NMR, cross polarization, and superconducting magnets during the 1960s and 1970s greatly improved the sensitivity of the spectra. Schneider, Pivcova, and Doskočilová used ¹H MAS NMR for the study of polymers,⁴ and Schaefer and Stejskal⁵ were the first to combine MAS and cross polarization for the ¹³C NMR of organics.

The field of molecular sieves has particularly benefited from the introduction of MAS. Molecular sieves are a family of porous open-framework solids which includes zeolites as well as materials derived from aluminum phosphate. Zeolites are built from corner-sharing SiO₄ and AlO₄ tetrahedra linked by the apical oxygen atoms to form frameworks of high internal surface area with regular channels and cavities of molecular dimensions. Their microporous structure enables zeolites to be used as sieves (as they can only adsorb molecules of certain size), cation exchangers, and catalysts for cracking, hydrocracking, oxidation, and isomerization of hydrocarbons. Most synthetic molecular sieves are microcrystalline and thus difficult to study by conventional methods of structural elucidation.

I had been working on molecular sieves at Imperial College, London since 1969 with R. M. Barrer, the pioneer in the field. In late 1979 the first high-resolution ²⁹Si MAS NMR spectra of zeolites measured jointly by groups led by Lippmaa (Tallinn, Estonia) and Engelhardt (Berlin) were shown as a poster at an obscure conference in the then East Germany.⁶ I had just moved to Cambridge, and was greatly excited by these results. The head of my Department, Professor (now Sir) John Meurig Thomas suggested to C. A. Fyfe, then at the University of Guelph, Canada, that we embark on a joint project. We began work on 9 January 1981. Several other research groups, notably those at EXXON (led by Melchior), Shell-Amsterdam, Leipzig (Pfeifer and Freude), Namur (Derouane and Nagy), Nijmegen (Veeman), and Paris (Fraissard) embarked on their own investigations. I have been interacting with many of these workers and was privileged to witness the rapid development of the field at first hand.

MAS NMR opened a completely new layer of insight into the structure of molecular sieves, and for several months one

could simply take a sample off the shelf to obtain results which were novel, fascinating, and important. Framework Si in zeolites is four-coordinate, and thus there are five different possible environments of a silicon atom: Si(OAl)₄, Si(OAl)₃(OSi), Si(OAl)₂(OSi)₂, Si(OAl)(OSi)₃, and Si(OSi)₄. Accordingly, the ²⁹Si MAS spectra are normally composed of up to five signals corresponding to these structural units.^{7–11} The Si/Al ratio of the zeolitic framework can be calculated from the spectra, and the distribution of Si and Al atoms in the structure, which has important catalytic consequences, can be determined.⁸ By comparing (Si/Al)_{NMR} values with the results of chemical analysis, which gives bulk composition, the amount of extraframework aluminum in chemically modified zeolites can be determined.^{9,10} The fact that the ²⁹Si chemical shift is related to the T–O–T angles and mean Si–O bond distances in zeolitic frameworks is also useful for structural studies.^{12,13}

The situation in highly siliceous zeolites, such as silicalite/ZSM-5, is very different, because there is little or no aluminum present. ²⁹Si MAS NMR spectra are composed of Si(OSi)₄ signals corresponding quantitatively to nonequivalent sites for silicon.¹⁴ In the case of silicalite as many as 22 of the 24 inequivalent silicons can be distinguished by NMR. The fine structure of the spectra depends on the temperature and is also affected by the presence of adsorbed organics.^{15,16} Thus NMR monitors subtle local rearrangements of atoms in the structure, an effect which cannot be readily studied by X-ray diffraction.

²⁷Al MAS NMR spectra of many natural and synthetic zeolites were measured soon after, providing new insights into the chemical status of aluminum. At first, the spectra were in apparent disagreement with the combined results of ²⁹Si MAS NMR and chemical analysis, but it was soon shown that ²⁷Al spectra must be measured at high fields and with very short radiofrequency pulses in order to be quantitatively reliable. ²⁷Al MAS NMR distinguishes between four- and six-coordinate aluminum (the latter is present in chemically treated zeolites), while quadrupole nutation NMR allows different Al species to be monitored.¹⁷

The Brønsted acidity of zeolites, responsible for their catalytic activity, arises from the presence of accessible hydroxyl groups associated with framework aluminum ('structural hydroxyls'). The acidic protons are relatively far apart which considerably reduces their dipolar interaction and important information on the chemical status of hydroxyl groups in dehydrated zeolites has been obtained by ¹H NMR, mainly by the Leipzig group. Extensive ¹H MAS NMR measurements of zeolites¹⁸ have led to the assignment of the various proton resonances. ¹H NMR of static samples can also probe the geometry of the Brønsted acid site using the moment method.

¹³C MAS NMR spectra of organic molecules intercalated in zeolites established that the templating tetrapropylammonium cations in zeolite ZSM-5 are located at channel cross sections in such a way that two hydrocarbon chains extend into the straight channels and two into the zigzag channels.¹⁹ ¹³C MAS NMR spectra identify 29 different organic species in the intracrystalline space of zeolite ZSM-5 during the catalytic conversion of methanol to gasoline and monitor their fate as a function of time and temperature; demonstrate the reality of product shape selectivity in a zeolite and the presence of a new type of shape selectivity; and distinguish between mobile and attached species.^{20,21}

There has been much interest in the use of ^{129}Xe (spin $I = \frac{1}{2}$ and 26.4% natural abundance) as a probe for investigating microporous materials.^{22,23} The technique can monitor sample crystallinity and is sensitive to the size and content of the cavities and channels.

A new challenge for NMR came in 1982 with the discovery of the AlPO_4 molecular sieves, porous equivalents of aluminum phosphate built from alternating AlO_4 and PO_4 tetrahedra. Incorporation of an Si source into the synthetic gel results in the formation of silicoaluminophosphates, SAPO, and the incorporation of a metal into AlPO_4 and SAPO gives the MeAPO and MeAPSO sieves, respectively. VPI-5, containing 18-membered rings of Al and P atoms, has considerable potential for the separation and catalytic cracking of large molecules. Cloverite, a gallophosphate with 20-membered rings, is the most porous molecular sieve prepared so far.

The AlPO_4 sieves are a challenge to solid state NMR, given the wide variety of new crystal structures and the presence of two kinds of 100% abundant nuclei (^{31}P and ^{27}Al) in close proximity.²⁴ Also, some Al atoms in AlPO_4 may be five or six-coordinate, which makes possible a wide range of structures. Another challenge is the strong quadrupolar interactions of ^{27}Al . In the last decade AlPO_4 sieves have been studied in many countries. ^{27}Al double rotation (DOR), a technique in which the sample is rotated around two different axes simultaneously, can monitor the structure of these materials,²⁵ and spin echo double resonance (SEDOR) can establish the relative spatial disposition of spins.

I am confident that advanced methods, such as 2D solid state NMR and laser-assisted techniques, will soon be employed to resolve many hitherto inaccessible problems of molecular sieve chemistry. The field is certain to flourish in the years to come.

Knight, Walter D.: The Knight Shift

Walter D. Knight

University of California, Berkeley, CA, USA

INTRODUCTION—HOW TO FIND A THESIS

I received the M.A. degree in physics at Duke University in 1943, and completed course requirements for the Ph.D. Then there was an interruption during 1944–45 when I joined the US Navy, saw small parts of the world on radar screens, and learned a lot about electronics. Subsequently I accepted a position as an Assistant Professor at Trinity College, Hartford, to work under Professor F. W. Constant, who had been one of my teachers and M.A. thesis supervisor at Duke. In seeking a way to complete the doctorate, I consulted Norman Ramsey who was Head of the Physics Department at Brookhaven National Laboratory. He pointed out that molecular beam magnetic resonance (MBMR) had been the preferred method for measuring nuclear moments¹ because of the high accuracy obtainable. However, the new methods based on the nuclear magnetic resonance techniques of Bloch and Purcell had the combined advantages of accuracy, simplicity, and sensitivity for bulk solid or liquid materials.

My conversations with Ramsey resulted in a summer (1948) position for me in the newly established Nuclear Moments Laboratory at Brookhaven. Bill Cohen, who like Ramsey had been a student of Rabi, was running the nuclear moments program. Bill suggested that I visit Bob Pound's lab at Harvard to learn about his marginal oscillator-detector, which was tunable over the wide frequency ranges needed to search for nuclear magnetic resonances. At the time, interest in nuclear moments was stimulated by the recently developed nuclear shell model. The problem was interesting and I decided to work along these lines hoping that a specific thesis topic would emerge.

In the rest of this article I will concentrate primarily on some related pieces of work which were intimately known to me during the 1950s and 1960s. Some of this is of course out of date, but it is of historical interest. References 1, 4, 6 and 16, which cover that period of time, give extensive coverage of the problems to be discussed, and may be consulted for details and further references.

SEARCHING FOR A RESONANCE

Bill Cohen designed and oversaw the construction of a suitable electromagnet, and I constructed a marginal oscillator based on Pound's circuit, with generous assistance from Bob on details. Thanks to plenty of training in electronics in the Navy radar programs, I found the construction easy and we found a proton resonance on our first attempt. However, it was difficult to maintain stable oscillation and sensitivity over wide frequency ranges, and so I decided to try a simpler circuit based on the cathode-coupled oscillator. Later, I explained the

new oscillator to Pound, who liked it and put his student George Watkins to work analyzing it and constructing an improved version, which came to be known in the trade as the 'Pound Box'.² The summer was soon over, and I returned to teaching at Trinity College. During the college year I spent many weekends traveling to Brookhaven improving the NMR system, returning to Hartford in time to teach Monday morning classes. The following summer (1949) I resumed the search for nuclear magnetic resonances at Brookhaven.

The first search was for resonances in antimony, which has two isotopes ¹²¹Sb and ¹²³Sb having different nuclear spins and magnetic moments—hopefully, we could bag two birds in one search! The first run was on a sample of antimony trichloride.

A good signal appeared to the delight and excitement of all in the lab, but unfortunately the observed resonance occurred nowhere near the frequency expected from the spectroscopic magnetic moments. Could it be an impurity? ... we dumped the sample and ran the empty test tube ... the signal persisted ... what is in Pyrex glass? ... boron! ... sure enough, the observed frequency was close to that expected for boron ... for a double check we removed the test tube entirely, which eliminated the boron signal ... then a previously unseen signal appeared near the frequency which Pound had reported for ⁶³Cu signals originating within the rf skin depth of the copper resonance coil ... but our observed frequency was about 20 kHz higher than what is expected from the standard tables of nuclear moments ... were there any other known moments close to copper? ... no ... was there an error in the tables? ... no ... In order to be sure of the effect we constructed a sample mixture of dry powders of copper metal and cuprous chloride. The resulting experimental resonance profile showed two well-resolved peaks, with the resonance for the pure metal appearing approximately 20 kHz above the resonance for the nonmetallic salt, around a 10 MHz average frequency. The measured relative shift was 0.23%.

Later that day Sam Goudsmit, who was Director of Brookhaven at the time, came by the lab to see the new results. I asked his advice whether I should pursue the search for new magnetic moments or continue studying the shift. He replied that naturally new physics should be more productive than another moment in the tables, and we returned to the experiments this time to determine what was shifting and why. In a flurry of activity in the next few weeks we investigated several other metals, including sodium, aluminum, and liquid gallium, each with its unique shift, and determined that isotopic pairs such as ⁶³Cu and ⁶⁵Cu possess equal shifts and that the fractional frequency shift was independent of the resonance field.³

A THEORY TO MATCH THE EXPERIMENT

Charlie Townes had moved to Columbia, and was spending time at Brookhaven that summer. He mentioned some of his recent work on hyperfine structure in molecules, and suggested that the NMR shift in metals might result from a hyperfine interaction between the magnetically polarized metal conduction electrons and the magnetic moments of atomic nuclei. The hyperfine field should augment the applied field and shift the resonance to a higher frequency. He suggested I try to estimate the magnitude of the effect in terms of the Pauli

electronic paramagnetism and the contact term for s-electron hyperfine interaction. I studied up on hyperfine structure, located Goudsmit's formula for the contact interaction, and got a result which agreed quite well with the experimental shift for sodium. In further discussions, Charlie took me to the article of Sommerfeld and Bethe in the 'Handbuch der Physik' and explained how the atomic hyperfine structure differs from the corresponding average for electrons at the Fermi surface of a metal. The average contact hyperfine field at the nucleus for an electron at the Fermi surface is⁴⁻⁶

$$\Delta B = (8\pi/3)[\chi_p V_0 B] P_F \quad (1)$$

where χ_p is the Pauli susceptibility per unit volume, V_0 is the atomic volume, and B is the applied magnetic field. The quantity P_F is the probability density for the s electron at the nucleus, averaged over electrons at the Fermi surface. The relative frequency shift, $K = \Delta f/f = \Delta B/B$, and the above equation may be used in several ways, depending on what quantity is to be obtained. For example, in metals where χ_p can be measured directly, P_F may be calculated from equation (1).

Having established that all the other metals studied showed comparable shifts of a few tenths of a percent, we were surprised to find no measurable effect in beryllium. Charlie arranged a consultation with Conyers Herring,⁵ who had recently published an article with Hill on the electronic structure of Be. Herring believed that the hyperfine field, equation (1), is low because of the strong p character (low P_F) of the wavefunction and also an abnormally low density of states (low χ_p) at the Fermi level.

In early investigations we studied the metals Li, Be, Na, Al, V, Cu, liquid Ga, and nonmetallic white phosphorus.³ The shift in white P compared to the nonmetallic phosphorus trichloride was approximately 0.1%. Ramsey¹ recognized that the observed nonmetal (chemical) shifts were caused mainly by Van Vleck orbital paramagnetism, which produces a smaller hyperfine field than does the contact interaction. Later¹ Bill Dickinson reported shifts depending on solution concentration, and Warren Proctor et al. reported shifts in several chemical compounds.

THE NUCLEUS AS A NONINVASIVE STRUCTURAL PROBE

While I was completing my thesis during the spring of 1950, I made several trips to New York to consult with Charlie Townes, who continued to be my informal adviser providing me with strong support. Charlie told me that he had given a talk in about 1949 with a title something like 'The Nucleus as a Probe of Structures'. Understanding that 'structures' include molecular and crystalline structures and electronic structures as well, the probe idea became the main theme of NMR experiments. The NMR and quadrupole coupling energies are in most cases negligible in comparison with atomic and molecular binding energies. Consequently the resonance experiments can be used to measure local internal fields in materials, without disturbing the basic structure of the system under study.

The NMR lineshift K in metals, named 'Knight shift' by Bloembergen,⁶ is a phenomenon unique to the metallic

state since it depends on conduction electrons, and it enables a practical analytical technique for probing systems endoscopically. The Knight shift has been used in many studies, including the melting of metals, metal-insulator transitions, normal-superconducting transitions, and phase transitions and magnetic couplings in metal alloy systems.

ANALYSIS OF ELECTRONIC AND GEOMETRICAL STRUCTURES

When I moved from Hartford to Berkeley in 1950, the Physics Faculty, particularly Owen Chamberlain, Emilio Segre, and Charlie Kittel (who arrived about the same time as me), were generous in their support for a new young colleague. Bob Brode gave me a couple of research labs, and I received for start-up a few kilobucks, which was around 1% of present custom. Most of this provided for construction of a permanent magnet and materials. I built the electronics.

I was also greeted by three graduate students who were all fired up and ready to join the exciting new game of NMR physics. We planned projects for the three students to work on Knight shifts in alkali metals, in metallic alloys, and chemical shifts in phosphorus. We organized a seminar on NMR, including some interested chemists. For a while, the seminar consisted mainly of a series of presentations by Al Overhauser on electron interactions in metals and the 'Overhauser effect', the enhancement of the nuclear polarization by interaction with the much larger conduction electron polarization. It was exciting to be led, chapter by chapter, through Al's thinking in the early stages. Actually there was considerable skepticism about the effect, and as usual most of the community waited for a successful experiment, which required prior observation of the electron spin resonance in a simple (alkali) metal. This took place in Art Kip's lab down the hall in Berkeley. Frank Abell suggested they should look for the ESR of sodium. I encouraged Frank to give them one of our ultrasonically produced fine particle sodium samples. This he took to Kip, and shortly after that Kip and Griswold found the ESR in sodium. Later the Overhauser effect was observed in lithium by Carver and Slichter at Illinois.

Following the study of pure metals, we explored effects in well-known alloys, e.g. CuAl, both constituents of which possessed known Knight shifts. The preliminary results in Al-rich alloys showed two Cu resonances with shifts which were assigned respectively to known metallurgical phases. However, the Cu NMR in the Cu-rich region did not show the variation expected for a changing average electron density. This was later explained by Bloembergen and Rowland,⁶ who assumed that in the Cu-rich regions the electronic structure varied only locally in regions near Al impurities. The affected Cu nuclei would have occupied noncubic sites, with resonance lines greatly quadrupole broadened and not observed. The observed Cu nuclei showed the normal shift.

Referring to the Cu-rich region of CuAl, the Al NMR shift was greatly reduced compared with pure Al, and showed little dependence on concentration. The same was true of Ga in CuGa. In view of their quadrupole moments, it appears that the observed resonances of Ga and Al originated with atoms lying in a cubic environment, the electronic structure of which is

governed by Cu, with the further implication that the trivalent atom contributes but one electron to the conduction band.

PHASE TRANSITIONS, LATTICE DYNAMICS, AND QUADRUPOLE COUPLING

Pound's⁷ pioneering work showed how quadrupole splitting of the NMR resonance peak gives detailed information about the magnitude of the quadrupole coupling and the crystal axis orientations in aluminum oxide. Later, Bob Cotts,⁸ studying single crystals of ferroelectric potassium niobate, identified the cubic, tetragonal, orthorhombic, and rhombohedral phases and the transition temperatures, and compared the results with X-ray, optical, and dielectric measurements. The pure quadrupole resonance (NQR) of Nb was also observed.

The importance of lattice dynamics appeared in a study of NaTi-type intermetallic compounds, in particular LiAl.⁹ The absence of Knight shifts confirmed that the compound is nonmetallic. The NMR linewidths and intensities of both nuclei were strongly temperature dependent as a result of the rapid diffusion of the small Li ions whose thermal motion was facilitated by an approximately constant density of vacancies in the Al 'defect lattice', which includes slightly less than the stoichiometric half of the total number of atoms. The narrowing of the NMR line results when the thermal motion averages out the Li-Li and Li-Al quadrupole couplings, analogous to NMR linewidth narrowing seen in alkali metals by Holcomb and Norberg.⁶

It was unclear what to expect for quadrupole couplings in metals. Molecular calculations corresponded well with experiment,¹⁰ but how to estimate the effects of the conduction electrons in metals? The first observation was of quadrupole satellites¹¹ astride the NMR in polycrystalline Be metal. Mel Pomerantz and T. P. Das¹² invented a simple band structure method for determining the effective charge at the metal lattice points, and calculated the appropriate lattice sum for Be. We developed an interpolation based on Townes¹⁰ method and applied it to crystalline Ga metal. The observed NQR frequencies for the two isotopes turned out to be very close to the calculated values.¹³ Subsequently, Bob Hammond¹⁴ investigated the NQR of metallic Ga in the superconducting state, and found a small frequency shift as well as an enhancement of the relaxation rate¹⁵ just below the superconducting transition temperature.

It is evident that the probing nucleus is a versatile instrument, considering both the magnetic and quadrupole moments. It is also interesting to reflect on the importance of sample preparation for NMR experiments. The problems become increasingly difficult as smaller particle sizes are studied, as will be seen below in the case of superconductors.

SPIN-REVERSING SCATTERING AND SUPERCONDUCTIVITY

The BCS theory of superconductivity is based on conduction electron spin pairing, and implies a zero Knight shift at zero temperature. This raised a lot of questions and provoked a lot of discussion.¹⁶ Fred Reif¹⁷ performed a beautiful set of experiments showing that the shift K_s in superconducting Hg

approaches approximately two-thirds of the normal state value K_n as $T \rightarrow 0$. Theoretical arguments were developed^{18,19} showing that a nonzero value of K was to be expected. In particular, the spin-reversing scattering introduces a statistical spin coupling so that complete pairing at low temperatures has a low probability. While this was going on, we tried Reif's experiment on a specimen of mercury of particle size smaller than Reif's and got a result more like $K_s/K_n \rightarrow 2/10$, which further confused a difficult question. That experiment was not repeated because we didn't know how to make a uniform size distribution of small mercury particles. Instead we developed a method for producing quite uniform ~ 100 Å tin platelets deposited by evaporation on Mylar sheets which were folded into a many-layer 'Dagwood' sandwich of tin particles. We then measured K as a function of temperature with the result $K_s/K_n \rightarrow \sim 3/4$ as $T \rightarrow 0$,²⁰ implying that Reif's result was right in the first place. Later, when the experiments were extended to investigate the spin-orbit scattering lengths for several superconducting metals of different particle size and purity, the experimental results²¹ for K_s/K_n turned out to be in reasonable agreement with the relevant theoretical treatments.^{18,19} Abrikosov and Gor'kov²² developed a general theoretical framework involving a parameter which is based on the ratio of the inverse spin lifetime to the superconductor energy gap. Like other treatments of spin-reversing scattering it implies an indirect size dependence for the shift K_s in the superconductor, because of the effects of boundary as well as impurity scattering. Unfortunately, the experimental results for the very interesting case of aluminum were in disagreement.^{23,24} By this time the theorists knew what was right and lost interest in the experimental morass. Afterward the problems multiplied in the studies of type II and high T_c superconductors.

It appears that NMR experiments have been of unique importance in studying superconductivity, not necessarily by directly answering the crucial questions, but rather by generating further questions which will ultimately lead to improved understanding.

THE PENULTIMATE SHRINK—TRAVELING IN LILLIPUT

In the foregoing we have chosen a series of NMR problems to illustrate the wide range of fundamental situations which can be treated by employing the nucleus to probe electronic and geometrical structures. The order of choice has been partly related to the size of the object under study. Critical dimensions have depended on parameters such as rf skin depth in metals (microns), and superconducting penetration depth (hundreds of angstroms). The size realm closest to atomic dimensions is inhabited by the metal clusters containing up to thousands of atoms with critical dimensions depending on the Fermi wavelength (nanometers).

Following our adventures in superconductorland, we became interested in effects of pure smallness which had previously been considered by Fröhlich²⁵ and Kubo.²⁶ My interest in the small particle effects was reinforced by a visit to Nico Bloembergen, who told me about the recent work of Kubo.

The effect of spin-reversing scattering in nonsuperconducting metals can be described in the Abrikosov-Gor'kov²²

framework, with the basic parameter modified by replacing the superconductor energy gap with the average energy level spacing in the small particles. Experiments on copper²⁷ included specimens with diameters ranging between 25 Å and 110 Å. The observed decrease in the copper Knight shift, with decreasing temperature and particle size, indicates the existence of spin-reversing scattering. The larger copper particles were early examples of the recently discussed mesoscopic structures in which, depending on scattering lengths, quantum interference effects become important.^{28,29}

Recently, we have found³⁰ that the metal clusters (nanos-structures) have a periodic table of their own, with magic numbers signifying special stability, analogous to the rare-gas atoms and magic-number nuclei. The existence of elaborate and complex electronic structures in these smallest metallic systems promises still further developments in the fundamental understanding of metals.

The preceding discussions represent a long series of fundamentally related experiments which lead logically to next steps in the continuing exploration of the behavior of microscopic metal particles. Predictably, NMR studies of mesoscopic structures^{27,31} will merge with NMR and optical studies of clusters,³⁰ allowing further exploration of these neighboring microscopic size realms.

Kochelaev, Boris I.: Discovery of Electron Spin Resonance

Boris I. Kochelaev

Kazan State University, Kazan, Tatarstan, Russia

In May 1944 Eugeny K. Zavoisky submitted for approval his doctor's thesis, which contained the initial successful measurements of electron spin resonance in condensed matter.¹ The road to this discovery consisted of three stages: the development of a very sensitive method for measuring the energy absorption of radiowaves in substances; the search for nuclear magnetic resonance; and measurements of ESR itself.

These pioneering experiments were performed at Kazan University, one of the oldest universities of Russia, located in the city of Kazan on the Volga river.

METHOD FOR MEASURING A WEAK RADIOWAVE ABSORPTION

During his graduate and postgraduate work, Zavoisky studied peculiarities of high frequency (hf) radiowave generators. After 1933 his main interest shifted to the study of a substance by means of radiowaves. The first steps were connected with an investigation of hf field absorption in liquids by measurements of their heating. The sensitivity of this method did not satisfy Zavoisky and he was stimulated to use his own experience in radiophysics.

In 1936 Zavoisky suggested a very sensitive electronic method for measuring the energy absorption of radiowaves in condensed matter as an alternative to the existing calorimetric method.² The idea was based on the detection of variations in the working regime of the generator due to the absorption of its energy by the sample under investigation placed in the alternating field of the generator. Earlier Zavoisky had demonstrated by special experiments the linear relationship between changes of grid or anode circuit currents and the watt load on the generator, provided the load changes were small in comparison with the generator power. The change in grid current was recorded at first by a galvanometer connected in a bridge circuit; later a multistage amplifier of constant or alternating current was used. The first estimations of the sensitivity of this 'grid current method' (GCM) led Zavoisky to the value of the order 50 nW per scale division for a frequency of 10 MHz. The first applications of GCM by Zavoisky were connected with measurements of the ionization potentials of molecules in liquids and gases.

ATTEMPTS TO DETECT NMR

In 1940 the research activity of Zavoisky took a new direction. He was impressed by the great precision of nuclear magnetic moment measurements performed by Rabi in molecular beams using the magnetic resonance phenomenon.

Zavoisky anticipated that his highly sensitive method could be used to make similar measurements in solids and liquids despite Gorter's failure to do so. He involved colleagues from the Physics and Chemistry Departments—the theorist S. A. Al'tshuler and the physical chemist B. M. Kozyrev—in this work. This team was well prepared to solve the problem. The main scientific interests of Al'tshuler at that time were connected with the mechanical and magnetic moments of nuclei and their interactions. In particular, he had published a paper previously with I. E. Tamm in which the existence of the magnetic moment of the neutron and its value and sign had been predicted correctly.³ Kozyrev had participated earlier in Zavoisky's measurements of the electrical absorption of radiowaves in liquids.

They decided to search for the proton magnetic resonance in water. It was not absolutely clear whether the spin relaxation of protons was effective enough to transfer the radiowave energy to the thermal bath. Theoretical estimations of the nuclear spin relaxation time given by Heitler and Teller predicted a value of many years, which did not provide much optimism. Zavoisky and his colleagues thought of special tricks to avoid this difficulty: they undertook measurements of concentrated solutions of both copper and manganese salts instead of pure water and in addition they used flowing water. A shortening of the proton relaxation time was expected due to interactions with paramagnetic ions.

Zavoisky was able to detect the proton magnetic resonance in May/June 1941. However, he did not achieve good reproducibility for the results at that time. This corresponded with the arrival of World War II in the former USSR and most of the institutions of the Academy of Sciences had to move from Moscow and Leningrad to Kazan University. Zavoisky's laboratory closed down and Al'tshuler joined the army as a volunteer. It is a pity that they did not have several months more to complete their task.

At this stage, it is perhaps pertinent to ask why these first NMR measurements were not stable? The answer is not quite clear, but it is certainly connected with difficulties in detection of the resonance signal using a galvanometer without constant magnetic field modulation. The latter was devised by Zavoisky two years later for his ESR measurements. Al'tshuler and Kozyrev also mentioned later the inhomogeneity of the external magnetic field. Zavoisky never discussed this question himself. Zavoisky looked through the papers of Purcell and Bloch and their colleagues, where the observation of NMR was reported, in the presence of Al'tshuler. According to his evidence, these publications did not cause any displeasure to Zavoisky. On the contrary, he was pleased with the fact that their techniques were approximately the same as his own.

THE FIRST MEASUREMENTS OF ESR

Zavoisky was only able to resume his research work in 1943. He did not continue the search for NMR but instead began studies of paramagnetic relaxation in orthogonal fields. It is not clear whether these experiments were conducted with the intention of detecting ESR. In fact, in the paper describing the first results of this study,⁴ submitted for publication on 4 February 1944, we find other arguments: 'Taking into consideration that the paramagnetic relaxation in perpendicular fields was investigated not enough and having in mind further

measurements of the nuclear magnetic moments, we have decided to repeat the mentioned above Gorter's experiments ... using the method to measure the high frequency field absorption, which is much more sensitive than any calorimetric one.' It seems that NMR measurements were still attractive. At first they wanted to test the sensitivity of GCM. In fact, the technique was essentially the same. The grid current of the hf generator (35 MHz) was still measured by means of a compensated galvanometer. The static magnetic field of up to 1300 Oe was created by the electromagnet. Powdered samples of manganese, chromium, and copper salts were placed in the field using a quartz or glass test tube. Measurements were performed at 81 K and 219 K. The reported results were very similar to Gorter's findings concerning paramagnetic relaxation in perpendicular fields. Not a single word can be found about ESR.

At the end of 1943 Zavoisky introduced very important modifications to his methodology. By using a solenoid instead of the electromagnet he provided a smooth variation of the constant magnetic field at low values. Additional modulation of this field allowed the use of multicascade amplifiers for the output and registration of the absorption signal by means of an oscillograph. One should bear in mind that the electron Larmor frequency of 35 MHz corresponds to the magnetic field $B_0 \sim 12$ Oe, i.e. the region of the rest fields of the electromagnet. The wavelength of the generator could also be varied from 200 to 18 m (1.5 to 17 MHz). Evidently Zavoisky was preparing to search for electron spin resonance.

Very soon absorption peaks were detected in manganese and copper sulfates, and in anhydrous chromium chloride. Measurements of the magnetic field at the absorption maximum versus the generator frequency gave a strict linear relationship between them. The position of the maximum was independent of the temperature from 300 K to 90 K, whereas the ordinates of the curve were proportional to $1/T$. The absorption peak disappeared when the constant field became parallel to the alternating field. The same results were obtained for aqueous solutions of manganese salts. All these findings demonstrate the existence of electron spin resonance or, according to Zavoisky, 'magnetospin resonance'. However, the resonance position could not be measured correctly at these low frequencies, and in the same year Zavoisky undertook new measurements at wavelengths of 32 and 65 cm (approximately 0.5 and 1.0 GHz). One of the curves obtained for the absorption derivative for copper sulfate at room temperature is shown in Figure 1. These results were presented in the supplement to his thesis¹ in October 1944.

In January 1945 Zavoisky repeated his experiments in the Institute of Physical Problems in Moscow by invitation of P. L. Kapitza. The results of ESR measurements in anhydrous copper chloride at a frequency of 133 MHz for temperatures in the range 20–300 K were published for the first time in a short paper.⁵ These experiments helped to overcome the skepticism of some Moscow physicists. Later transition to 10–14 cm wavelengths made the ESR signal much more pronounced.⁶ The resonant absorption curve for manganese sulfate at 2.75 GHz is shown in Figure 2.

Zavoisky's next step was the detection of the paramagnetic resonant dispersion curve using the 'crossed coils' induction method.⁷ The nature of ESR line broadening due to spin–spin interactions was correctly interpreted in collaboration with Al'tshuler and Kozyrev.⁸ Zavoisky also managed to observe

Figure 1 One of the first ESR signals, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ at 300 K and 0.46 GHz. (Redrawn from E. K. Zavoisky, 'Magnetic Radiowave Spectra of Paramagnets', Supplement to *Thesis*,¹ Kazan University, October 1944)

Figure 2 ESR signal at 2.75 GHz for MnSO_4 , at a temperature of 300 K. (Redrawn from E. K. Zavoisky, *J. Phys. USSR*, 1946, **10**, 197)⁶

'forbidden' ESR lines corresponding to transitions between spin levels with changes in the magnetic quantum number $\Delta m = 2, 3, 4$ for the Mn(II) ion.⁹ It is also worth mentioning that all the spectrometers employed by Zavoisky (including the generators) were constructed by his own hands.

In 1947 Zavoisky moved to Moscow and, at first, together with other colleagues developed methods to measure superfast processes with time resolutions in the range 10^{-12} to 10^{-14} s. After 1958 he was mainly interested in plasma physics in connection with the problem of controlled thermonuclear fusion. The 'resonance ideology' of Zavoisky was also displayed in this new field. He suggested the use of a magnetoacoustic resonance method for heating the plasma and EPR methods for its characterization.

Koenig, Seymour H.: I. I. Rabi, F. Bloch, E. M. Purcell, and the History of NMR and Relaxometry

Seymour H. Koenig

*Dartmouth-Hitchcock Medical Center, Hanover, NH, USA and
Relaxometry, Inc., Mahopac, NY, USA*

INTRODUCTION: RABI AND NMR IN ATOMIC AND MOLECULAR BEAMS

The instructions for contributors to these volumes note that this ‘encyclopedia will take advantage of the fact that 1945 saw the first successful NMR experiments (published in 1946)’. The reality, of course, is that the Nobel Prize for Physics was awarded to I. I. Rabi the previous year, in 1944, ‘for his discovery of a resonance method for recording the magnetic properties of atomic nuclei’. The initial publication,¹ in 1938, a letter titled ‘A New Method of Measuring Nuclear Magnetic Moment’, was followed shortly by a long paper² on ‘The Molecular Beam **Resonance** Method for Measuring **Nuclear Magnetic Moments**’ (emphasis mine).

In a radio broadcast which, because of wartime conditions, substituted for the Nobel ceremony, E. Hulthén noted that the Rabi technique—which clearly could be applied to electronic and molecular magnetic moments as well—was ‘as simple as it was brilliant’. Rabi’s approach involved beams of atoms or molecules in a vacuum. By introducing inhomogeneous magnetic fields² along the beam path, the specific trajectory of each particle as it traverses a long evacuated chamber becomes a function of its spatial quantization state. Inducing a transition in this quantization mid-course, by application of a resonant radiofrequency field, alters the particle trajectory and decreases the beam intensity (detectable by a variety of methods depending on the particular atom or molecule under study).

BLOCH, PURCELL, AND NMR IN CONDENSED MATTER

What was discovered in 1945 was NMR in condensed matter: Bloch et al.³ in liquid water (doped with ferric nitrate)⁴ and Purcell et al.⁵ in rigid paraffin. However, much of the necessary ‘cultural baggage’ was already in place. As noted at the 1952 Nobel ceremony for Bloch and Purcell, again by Hulthén, the Nobel Prize had recently been awarded to Rabi for his invention of NMR. Indeed, both Bloch and Purcell cite the beam method in their original publications.^{3–5} In addition, the magnitude of the proton magnetic moment was known, from beam methods,⁶ to six-place accuracy; Gorter⁷ (using calorimetry for detection) and Bloch (quoted by Rabi¹) had already attempted, albeit unsuccessfully, to find

the proton resonance in solids, and use of the rotating frame for discussing gyromagnetic motion was common.^{8–10} Indeed, all this had been accomplished before 1940, before World War II interrupted the normal evolution of scientific discovery but enhanced the advance of technology.

From 1940 to 1945, Rabi was Associate Director of the MIT Radiation Laboratory, concerned with the development of microwave radar. Bloch came east in 1944, from Los Alamos to the Harvard Radio Research Laboratory, indeed, in time to attend the celebration in Cambridge of Rabi’s prize. Purcell had been at the MIT ‘Rad Lab’ since 1940. Thus, both he and Bloch were immersed in the developments of the most sophisticated electronics of the time, including radiofrequency and microwave techniques and low noise detectors. As Rabi told it (private discussion, 1986), it was quite clear that—technically—the proton resonance could be detected in condensed matter, and that Bloch and Purcell could scarcely wait for the end of the war, each to try his own method—at opposite sides of the continent—to observe the proton moment. The major uncertainty was the magnitude of the proton spin–lattice relaxation time, since early estimates suggested that it might be so long that saturation effects would limit the rate at which the proton ensemble would absorb energy and thereby frustrate its detection. The Rabi beam method does not involve relaxation times; irradiated atoms and molecules are continually replaced by ‘new’ particles, much as in present-day measurements of blood flow in MRI (magnetic resonance imaging), experiments that are in a sense the condensed matter, high-resolution NMR, analog of the original Rabi beam experiment.

Bloch chose liquid water, reducing the solvent proton relaxation time by adding trace amounts of the paramagnetic solute ferric nitrate⁴ (thus foreshadowing the use of such solutes as agents for altering contrast in MRI), and detecting the dispersive (transverse) component of the proton signal in the 7–11 MHz range. He named the method ‘Nuclear Induction’. Purcell chose solid paraffin and the absorptive mode, using a sensitive radiofrequency bridge to measure changes in Q , i.e., the dissipation in the paraffin core of a cavity resonant near 30 MHz. The bridge was driven with a weak source, in expectation of a relaxation time of several hours. He referred to the method, not quite naming it, as resonance absorption.

What Bloch and Purcell contributed were nondestructive methods for the *precision* measurement of nuclear moments in condensed matter, on both an absolute and relative basis. It was certainly appreciated at the time that accurate determinations of nuclear moments would revolutionize the study of nuclear physics. Indeed, that the proton moment is ~ 2.8 -times the nuclear magneton was just one more anomaly in the nature of nuclear forces, along with their short range and the existence of a magnetic moment for the (uncharged) neutron. What was not anticipated, at the time, was the phenomenal contribution that precision measurements of nuclear moments, now called ‘high-resolution NMR’, would make; initially to chemistry, and, later, to biochemistry and clinical medicine. Indeed, Rabi noted (private discussion) that the emphasis at the Columbia University Physics Department during the 1950s would have been much different had he foreseen the ultimate applications of the discoveries of Bloch and Purcell.

ESR IN BEAMS, NMR IN WATER, AND THE ANOMALOUS ELECTRON g -VALUE

My personal involvement, starting at Columbia University in 1949, was with the first experiment to combine the Rabi and Bloch–Purcell NMR approaches, together with the Rabi analog of condensed matter ESR (electron spin resonance).^{11,12} It was known that the hyperfine splitting of atomic hydrogen was slightly larger than the value computed using the Dirac (relativistic) theory of the electron, and Breit¹³ had recently suggested that an ‘anomalous’ addition to the magnetic moment of the electron, $\sim 0.1\%$, could account for this discrepancy. Moreover, initial low-order computations of the ‘self-energy’ contribution to the electronic moment, a term arising from the motion of an electron through its own electric field, agreed quite well with the hyperfine anomaly. These were the first results of the new Feynman–Schwinger–Tomonaga quantum electrodynamics, and the good agreement of the low-order results made both measurements and computations to higher order desirable. P. Kusch, a student and early collaborator of Rabi,¹ confined to bed for some time because of vertigo associated with scarlet fever, conceived of an experiment to measure the electron g -value to high precision, and offered it to me as a thesis.¹² It was to win the Nobel Prize for Kusch in 1955, shared with W. E. Lamb, Jr. The concept was, in part, a Rabi magnetic resonance experiment, in which microwave transitions in a beam of *atomic* hydrogen (generated in an electric discharge) were to be measured at ~ 0.15 T; this is, in essence, an ESR experiment on a beam of free radicals. But it was more: the magnitude of the magnetic field was to be measured by the new Purcell NMR technique. A. Sachs had just joined the faculty at Columbia, bringing from Harvard the circuit of the ‘Pound Box’, a marginal oscillator with an output that was very sensitive to the Q of its resonance circuit. (This replaced the rf bridge used earlier.⁵) I was to build one and find the proton resonance in a sample of water, doped with manganese sulfate, contained in a vacuum-tight glass holder with a shape that approximated the beam geometry in the microwave transition cavity. Since Gardner and Purcell¹⁴ had recently measured the electron cyclotron frequency (proportional to the Bohr magneton) in a field calibrated by proton NMR, a combination of the two results would give the electronic moment in terms of the Bohr magneton (the electron g -value), precisely the quantity desired. The experiment clearly worked; after corrections to the proton resonance frequency for shape and susceptibility factors, and to the electronic transition for a range of relativistic effects, the electron g -value was now known with new precision. More than one decade later (1965), Feynman, Schwinger, and Tomonaga shared the Nobel Prize in (experimental) Physics for explaining the anomaly measured by Koenig et al.,^{11,12} an experiment initially conceived to test these very calculations.

RELAXOMETRY AND RELAXOMETERS

It was not until 15 years later, after having studied low-temperature electrical transport and inelastic neutron scattering in solids, that I saw another proton signal. This was during the renaissance in protein research that followed the discoveries of Watson and Crick. The question was whether there was

some means of detecting changes of conformation of solute protein (then a nebulous concept) by a physical technique. The answer was (particularly in retrospect) to measure solvent proton magnetic relaxation rates in solutions of protein, both diamagnetic and paramagnetic. One reference then in the literature¹⁵ indicated a solvent proton relaxation rate that was a nonlinear function of the paramagnetism (oxidation state) of ceruloplasmin, a Cu-containing blood-plasma protein, indicating (to me) the existence of a cooperative effect within each protein molecule, i.e., a conformation change. All that was necessary was to develop the appropriate instrumentation, find a set of good problems, and extend the theory of relaxation to these macromolecular systems!

It should be recalled that, in the early days of NMR, before it could be used to study small solutes with high precision, particularly those containing paramagnetic metal ions, measurement of the influence of solute on solvent relaxation was a standard approach, starting with the classic work of Bloembergen et al.¹⁶ In time, this approach was used anew, and became the method of choice for investigating large solute molecules as the techniques of high-resolution NMR improved and dominated the study of smaller solutes. It remains the best approach for the study of complex macromolecular systems, including tissue.¹⁷

Over the years, with the collaboration of many—and the timely invention of MRI (which depends for its efficacy almost entirely on tissue-dependent relaxation rates of the protons of mobile tissue water)—all this has come together. The combination of activities is now a recognized field, named ‘relaxometry’ so named by me at an NIH workshop about a decade ago. The specialized instruments to measure relaxation rates as a function of field and temperature were named ‘relaxometers’.

R. D. Brown III, a long-time associate, has worked steadily through the years to develop a relaxometer appropriate for our studies, which are mostly on liquid-like rather than solid state samples. The relaxometer is based on early ‘field cycling’ ideas of A. G. Redfield.¹⁸ A major improvement came in the mid-1970s when the relaxometer was first attached to a large main-frame computer, not only for data-logging but for automated control of the experiments. This gave a 10-fold improvement in the rate of data acquisition and analysis, and a concomitant improvement in accuracy, allowing the first demonstration of a major conformation change that related to protein function. The protein was concanavalin A,¹⁹ a bean lectin with a strong, but selective, affinity for certain sugars. We showed that, near equilibrium, the protein could exist in two conformations, distinguished by a *cis–trans* isomerization. One conformer carried the sugar-affinity but required the binding of two metal ions to make this conformer have the lower energy. It took four months of running time with the improved relaxometer to obtain data that yielded the equilibrium binding constants for metals and sugar to the two conformers. It took additional time to measure, using the automated instrumentation, the kinetics of metal-ion and sugar binding and, above all, the kinetics of the newly discovered conformation change. In addition to elucidating the structure–function relationships of transport and storage proteins, relaxometry has helped clarify the mechanisms of enzyme action in many systems, a particular case being carbonic anhydrase,²⁰ a protein that appeared to hydrate carbon dioxide at a rate faster than the limitations imposed by the diffusion of substrate.

With the advent of MRI, there were new demands for relaxometry measurements and for relaxometers. The advent of personal computers about a decade ago made it possible for Brown to develop a stand-alone version of our relaxometer, clones of which are now in Mons (Belgium), Florence (Italy), University of Illinois (Urbana), Dartmouth (Hanover), and NY Medical College (Valhalla). These instruments not only serve the entire pharmaceutical industry in their developments of magnetic contrast-enhancing agents for MRI, but are the means through which the molecular basis of tissue-specific contrast in MRI has finally been elucidated.^{17,21}

Kowalewski, V. J.: Tribulations of a Young Physicist with a New Phenomenon

V. J. Kowalewski

University of Buenos Aires, Buenos Aires, Argentina

Having obtained my Ph.D. degree in physics in 1948, I was appointed to the University of LaPlata as 'Adjoint Professor' (that means just a helper) to Professor A. Balseiro (whose name nowadays adorns the best physics institute of our country).

The Physics Department of this Faculty was at that time in the charge of a distinguished German professor, Dr. Richard Gans. He specialized in magnetism, having been an expert in this field at the AEG Company. When the moment arrived to talk about my research obligations, he told me that 'It is already time to begin the study of nuclear magnetism,' and he told me to read 'a certain paper by Felix Bloch' and to give a seminar on the subject. This was achieved after quite a short time (since I found Bloch's paper easy to understand), but I was then required to try to repeat his experiment.

Having also read Purcell's paper, I found Purcell's circuit simpler to build than Bloch's 'paddle' device. So I built an rf bridge in a simple aluminum box (the only trouble was to find a differential capacitor).

Of course, the main problem was the magnet. At that time there was a nice 8-in. magnet in the Institute, but it was used for Zeeman effect studies. So I had to content myself with an old, Dubois magnet, barely 3 in. in diameter. I am still amazed that I was eventually able to see an NMR signal with such a magnet!

The next step was to obtain the electronics. Having made a preliminary field measurement of the electromagnet (which was powered by a pair of car batteries), I decided to work at 15 MHz. The Radio Department of the Faculty lent me a nice communications receiver and a standard rf generator, built for receiver calibration purposes. It took me about six months to get the system working. (At that time I was not yet a full-time professor.)

The bridge behaved nicely as a microphone. I could hear my voice in the receiver speaker when the bridge was attenuated

below 80 db, but there was no NMR signal. Besides, when the bridge was adjusted in this way, I got a nice 'figure eight' Lissajous pattern on the scope!

I measured the noise figure of the receiver. I wrote to Prof. Torrey for advice which I got in plenty, but to no avail! My conclusion was that the 'figure eight' was due to the 100 Hz sidebands of the rf generator, which had its power supply filtered adequately for radio work, but not enough for my purposes.

I informed my Director, telling him about the necessity of improving somehow the power supply of the generator. The answer I got was (as to be expected): 'Try again'.

I was desperate.

Then, on a certain Saturday, a friend of mine came to look at my work and asked me what was I doing. I told him I was just cursing this . . . apparatus on which, instead of a 'resonance' curve I only got an 'eight'. And I showed him the 'eight'. Suddenly he asked me: 'What is that?' We both saw a small absorption signal running back and forth along the 'eight' when the magnet current was swept. It was the signal I was looking for!

Now I was determined to get rid of the 'eight'. So I went to the Radio Department for advice, and they gave me more than that. At that time there were still some big 90 V batteries for country use available. They had three of those, which they gave me. It was an easy matter to disconnect the 'well filtered' 300 V power supply and to put the 270 V battery instead.

Then, at last, I got a beautiful NMR signal! My Director was very pleased!

Corollary: A new political government decided that neither my Director nor I were necessary in the Faculty. So I went to work in our Atomic Energy Commission . . . under the same government!

P.S. I am now in charge of a 500 MHz supercon.

Specialties: instrumentation, INDOR and signs of J couplings.

Kumar, Anil: Development of Two-Dimensional NMR—My Perception

Anil Kumar

Indian Institute of Science, Bangalore, India

The development of both one- and two-dimensional FT NMR created a revolution in the practice of NMR and provided a turning point in the methodology and applicability of NMR to complex systems such as biomolecules. Whereas the former made it possible to record the spectra of large molecules at low concentrations, the latter also made it possible to assign the spectra to individual nuclei and to obtain information on internuclear distances, leading to structure determination. Even though conceptually both are straightforward, each took several years to materialize. The Fourier relation between the spectrum and the free-induction decay had been known from the early days of NMR, but it was only in 1965 that Richard Ernst showed that it is faster (and better) to undertake time domain spectroscopy. Similarly one could easily think of two-dimensional Fourier analysis, but the idea had to wait several years for its germination and utilization.

It was at a summer school at Pulé, Yugoslavia in 1971 that Jean Jeener of Belgium proposed the rather esoteric idea of two-dimensional Fourier analysis of a two-pulse experiment. Jeener seems to have put the idea aside and never published it. I joined Ernst's group in Zürich in 1973 and started cross-polarization experiments in solids. Sometime during 1973 Ernst wondered whether to start on Jeener's idea, and finally decided to pursue it but, initially, for an entirely new purpose.

In 1973, Paul Lauterbur described a technique for obtaining images by NMR, using steady field gradients and projection reconstruction. In 1974, Ernst came up with the most outstanding idea of not only using Fourier spectroscopy in one dimension but with the idea of pulsed and switched gradients in two or three dimensions and the use of multidimensional Fourier analysis. Ernst wrote a few subroutines, Dieter Welti wrote others and I did the experiment. The gradients were applied by switching off the current in the linear shim coils of an electromagnet. A crude 64×64 matrix image of two tubes of water was printed on a teletype by digitizing the intensity into blanks, dots and alphabets. We laughed at the experiment and published it without patenting. This Fourier image is the first documented two-dimensional spectrum. After this we turned our attention to two-dimensional (2D) spectroscopy. Enrico Bartholdi worked on the theory, Walter Aue on protons, and Luciano Müller and I on carbon–proton experiments.

The first experiment was a simple one, resolving the ^{13}C spectrum of *n*-hexane into one coupled in one dimension and decoupled in the other. The spectrum, with the data plotted in stacked-plot form with the overlap of the back traces blanked out using white ink, had an immediate appeal. Kurt Wüthrich, on seeing the spectrum, immediately sat down with his head in his hands. The potentials of the technique seemed to have hit him. He later collaborated with Ernst in exploiting 2D NMR for biomolecular studies and, as a result, accelerated its subsequent growth.

Several modifications were undertaken to the initial 2D-resolved experiment, first by removing the carbon-13 chemical shift from one of the dimensions by the use of a spin echo and later removing strong coupling artifacts by using only one-half of the echo period for *J* evolution. We called these experiments (i) and (ii). Later Ray Freeman and Geoffrey Bodenhausen also invented the same experiments but named them appropriately as 'spin echo' and 'gated decoupler' 2D spectroscopy. The experiments are now known by these names. The importance of appropriately naming an invented technique led to the 'naming-game' in 2D spectroscopy, a game already started by John Waugh for studies in solids.

The complete theoretical framework for 2D spectroscopy was developed and is contained in a comprehensive paper by Aue, Bartholdi, and Ernst (1976). This paper contains a detailed analysis of intensities, phases, connectivity of transitions, lineshapes, flip angle dependence, strong coupling effects, relaxation and field inhomogeneity effects, and most original ideas on multiple quantum transitions, their excitation in pulsed spectroscopy, and indirect detection using a 2D algorithm, all supported with detailed experiments. The foundation of 2D spectroscopy was thus firmly laid and the paper has become a Citation Classic, just as the 1D FT paper.

There had been other schools which contributed significantly to 2D spectroscopy. John Waugh's group at MIT gave the algorithm for separated local field 2D spectroscopy in solids and Ray Freeman's group at Oxford contributed to liquid state 2D NMR almost from the beginning.

At Zürich, 2D-resolved spectroscopy was extended to proton–proton systems and one could, for the first time, obtain self-decoupled proton spectra using a 45° projection of a spin echo 2D spectrum. As I was just getting involved with the influence of strong couplings in such spectra, I left Zürich and joined the Indian Institute of Science, Bangalore in 1977. I completed the analysis of the strong coupling effects in 2D spin echo spectra at Bangalore and confirmed them experimentally.

In the meantime, back at Zürich, work was going on at a hectic pace. Correlation spectroscopy was extended to heteronuclear systems, basic ideas of coherence transfer and sensitivity enhancement were established, and multiple quantum spectroscopy was studied in greater detail. A crucial collaboration started between Ernst and Wüthrich with the aim of applying 2D NMR to biomolecules. Kuniaki Nagayama from Japan provided the initial impetus to this project by applying resolved spectroscopy to the study of biomolecules and by inventing spin echo correlated spectroscopy. In 1979, I joined this project for a year. I was fascinated by the way the nuclear Overhauser effect (NOE) was being exploited in Wüthrich's laboratory for the study of biomolecules. They were literally doing hundreds of 1D difference NOE experiments. I noticed a preprint by Ernst, Jeener, and others describing a new three-pulse 2D experiment for the study of chemical exchange. This was too important for me to ignore as I was convinced that that was also the 2D experiment for the study of NOE in biomolecules. I launched a fullscale effort to try to make it successful. There were many hurdles which form an interesting side story of their own. Finally it worked and its success was phenomenal. The 1D difference experiments were immediately given up and everyone wanted a 2D NOE spectrum of his biomolecule. The COSY experiment was rejuvenated and gave rise to NOESY–COSY diagrams. I remember the 1980 ENC meeting at Tallahassee, Florida where

ours was perhaps the only poster containing contour plots. A few years later one could hardly find a poster in an NMR meeting without a contour plot. The development of the 2D NOE experiment was perhaps the most important turning point in the development and applications of 2D NMR. It fueled a large-scale application of 2D techniques to the study of biomolecules, which in turn necessitated development of newer 2D techniques and their improvement.

The various developments and applications of 2D NMR during the 1980s resulted in the maturing of this field into fully-fledged practice and its acceptance as a viable tool for the structure determination of biomolecules in solution. The success of this algorithm has also been responsible for the development of higher frequency spectrometers and for NMR studies of molecules of a kind unimaginable up to the 1970s. Large computers and work stations have become integral parts of NMR hardware and NMR is now an accepted tool in biomolecular study, just as NMR imaging has become an

integral part of radiology. We now await, rather look forward to, the next revolution.

La Mar, Gerd N.: NMR of Paramagnetic Proteins

Gerd N. La Mar

University of California, Davis, CA, USA

The prevailing 'wisdom' has always been that integral paramagnetic molecules do not yield well-resolved or useful solution NMR spectra. The initial report of a solution NMR spectrum of an intact paramagnetic molecule occurred in 1957.¹ By the early 1960s there were appearing remarkable articles by the DuPont group of Phillips and Eaton defining the conjugation properties of a variety of organic functional groups in Ni(II) complexes. As a second year graduate student at Princeton in 1962, I was interested in theoretical aspects of hyperfine coupling constants when it was suggested that we instead measure such couplings by NMR, since this would yield both magnitude and sign. However, in order not to 'contaminate' with unpaired electrons the departmental Varian A-60, and because the fixed 2 kHz modulation introduced the cursed sidebands in the middle of the spectra, it was arranged with Bob Shulman that I would collect my spectra at Bell Labs. There I met Ernie Anderson who educated me on the virtues of a PAR lock-in amplifier and convinced me that the zero dB attenuation button for transmitter power on a DP 60 did, after all, have a practical use. Although by the middle 1960s the complexes of a variety of metal ions had been shown to yield well-resolved and informative NMR spectra, the NMR community continued to consider each successful report as just another exception, if not the last example.

The 1960s produced a spate of fruitful studies on inorganic transition metal complexes for which available synthetic methods allowed the necessary assignments. Biological applications were just starting, either with Mn²⁺-induced relaxivity, or on the heme complexes which yielded a wealth of information on the electronic structure of the isolated chromophore from hemoproteins. The relatively minor biological as compared to inorganic interest in these NMR studies was reflected in the first monograph on the subject in 1973, which devoted only ~10% of its coverage to biological applications.² However, it quickly became apparent that there was a distinct advantage for studying paramagnetic proteins, in that the hyperfine shifts for the prosthetic group afforded resolution not accessible on the available low-field spectrometers. The initial report of the NMR spectrum of a paramagnetic protein, ferricytochrome-*c*, was by Kowalsky in 1965, and was quickly followed by more extensive investigations on these and related hemoproteins by the research groups of Shulman, Wüthrich, and Redfield, and on iron-sulfur proteins by Phillips and co-workers.

The intrinsically high information content of hyperfine shifts was recognized early. However, with mounting piles of data on proteins, it also became clear that the assignments needed to interpret the data were elusive. The full realization of the experimental problems to attaining assignment resulted in a significantly waning interest in NMR of paramagnetic proteins, although not before a key report showed isotope labeling of the heme in myoglobin was practical. With the development of steady-state and time-dependent NOEs in diamagnetic proteins in the late 1970s, the lone representative of the

paramagnetic metalloproteins whose NMR spectra benefited from these advances was the class of ferricytochromes, investigated primarily in Wüthrich's lab,³ where the standard assignments in diamagnetic ferrocytochrome were carried over to paramagnetic ferricytochrome by saturation transfer. The broad-based success of this approach and the wealth of information on the control of the orbital ground state, however, while never so stated, left the impression that multipulse NMR methods were not applicable directly to a paramagnetic protein.

Our own entry to NMR of paramagnetic metalloproteins in 1977 was prefaced by a lengthy apprenticeship in elucidating the NMR properties of heme model compounds in order to lay the groundwork for interpretive bases for the protein spectra, followed by extensive isotope labeling of intact *b*-type hemoproteins that provided crucial assignments for testing multipulse methods. The first report of NOE within a paramagnetic molecule appeared by Redfield and Gupta in 1971, but was a relatively minor point in a study of magnetization transfer between the two oxidation states of cytochrome-*c*. The broad utility of NOE studies of paramagnetic metalloproteins was suggested to us in 1980, when we found that nonselective T_1 values are seldom single-exponential in paramagnetic proteins, implying that cross relaxation contributes significantly to the relaxation. With this impetus, we embarked on systematic studies of steady-state and time-dependent NOEs in both weakly and strongly paramagnetic proteins, using our previous isotope labeling work as a starting point to test the methods.⁴ While the initial studies focused on small proteins such as myoglobin and cytochrome (13–18 kDa), successful studies were eventually extended up to a 155 kDa peroxidase. While heme proteins served as important test cases for the methodology, similar studies were subsequently extended to all classes of paramagnetic proteins which exhibit well-resolved NMR spectra.

The last major hurdle to bringing paramagnetic proteins into mainstream NMR studies, the application of 2D methods, came more slowly and coincided with obtaining a suitable NMR spectrometer in 1989. The earliest 2D experiments involving a paramagnetic protein, as was the case for 1D NOE experiments, entailed extension of the assignments from ferro- to ferricytochromes by magnetization transfer. However, shortly thereafter we demonstrated that the NOESY experiment could directly yield assignments for ferricytochrome *b*₅, and cyano metmyoglobin. Because of the strong increase in cross relaxation with molecule size, profitable studies were eventually extended to both large (44 kDa) and strongly paramagnetic ($S = \frac{5}{2}$) proteins. The extension to spin correlation experiments followed quickly, and it is now accepted that 2D NMR will yield quantitative molecular structural, as well as unique electronic structural information on a variety of small to intermediate sized paramagnetic metalloproteins.⁴ In fact, by the beginning of the 1990s, the study of paramagnetic metalloproteins by modern NMR methodology, after a long tenure as a misunderstood orphan, has emerged as a fully fledged member of the arsenal of solution structural approaches to biopolymers.

Lambert, Joseph B.: The First Observation of Nitrogen-15 Nuclear Magnetic Resonances

Joseph B. Lambert

Northwestern University, Evanston, IL, USA

In 1962, when I began graduate studies with John D. Roberts, Caltech balanced the liberal requirement of no courses in one's major with the draconian requirement of three full year courses in a minor from a different department. After briefly flirting with astrophysics (quasars had just been discovered there), I settled on the more practical field of biochemistry, which at Caltech is a separate department. In the spring of 1963 I was sleeping my way through a year-long course on biophysics, having successfully survived light scattering and ultracentrifugation, when we finally reached spectroscopy. Professor Robert Sinsheimer got my attention, when in his lectures on NMR he mentioned how useful ^{15}N , with its spin of $\frac{1}{2}$, would be for biological systems. Moreover, he said that Roberts planned to initiate a program on the subject, since no ^{15}N resonance had ever been observed. When I asked Roberts's assistant Marjorie Caserio about it (I am sure that J.D.R. was out of town as usual), she mentioned that they had purchased a custom-made radiofrequency (rf) transmitter-receiver unit from Varian, but no one had ever used it. I found the V-4311 gathering dust on a shelf and decided to see if I could find a ^{15}N resonance. The frequency was 6.08 MHz for the 1.41 T magnet (14 100 G then).

By midsummer, George Whitesides was wrapping up his thesis work, so I had time on the HR-60 to set up the rf unit in place of the one we used for ^1H and ^{19}F . There was no procedure for finding resonances of entirely unstudied nuclei, but there was a procedure for finding the ^1H signal after the magnet had been turned off for cycling. It consisted of bringing the magnet to full power, turning on an oscilloscope with the spectrum condensed to a spot on the screen, and altering the magnetic field with a rheostat until the spot bounced. The bounce was the resonance whizzing by. If I stopped rotating the rheostat instantly upon seeing the spot, conversion of the oscilloscope from a spot display to a screen-wide display would reveal the resonance in all its glory. When Ken Servis and I tried this procedure with the ^{15}N unit and saw the spot bounce, my heart performed an analogous motion. The sample I used was commercial 8.57 M nitric acid containing 96.1% ^{15}N , in a 9.85 mm o.d. nonspinning tube. It was July 24, 1963, and this comprised the first observation of a ^{15}N resonance.

Advances came quite rapidly. Proper tuning and building a spinner assembly brought the linewidth from 10 Hz down to 1 Hz (cps then) with excellent ringing. I set about to synthesize a sequence of labeled molecules to survey chemical shifts, and within six months had studied nitrobenzene, aniline, acetamide, azobenzene, ammonia, azoxybenzene, potassium cyanide, and hydrazobenzene, among others. Protonation of the bases amongst these molecules led to an understanding of how the lone pair affects the chemical shift. I managed

to rig an audiooscillator at the ^1H frequency and observe the first proton-decoupled ^{15}N spectrum, by collapsing the quintet of NH_4^+ to a singlet. In early efforts I observed some odd negative peaks. As the nuclear Overhauser effect was unknown at the time (the gyromagnetic ratio of ^{15}N is negative), a wonderful opportunity slipped by. I originally used the nitric acid sample as the chemical shift standard, but the constancy of the resonance position of dry ammonia and its high field location led me to settle on it as the chemical shift standard, and it is still used as such today. All these exciting results were bundled up and sent to the *Journal of the American Chemical Society* as a communication, which was promptly rejected as being too mundane. Imagine biological NMR today without ^{15}N (apparently the referees could)! We published it in the *Proceedings of the National Academy of Sciences*.¹

The azoxybenzene sample had enabled me to measure the first coupling between two ^{15}N nuclei, 13.7 Hz over one bond.² A variety of systems with protons on nitrogen led to a relationship between the one-bond ^{15}N - ^1H coupling constant and the s character of the N-H orbital,² $s = 0.43J + 6$. Over the next year the development of chemical shifts and coupling constants continued.³ Gerhard Binsch began work on ^{15}N - ^{13}C couplings² and Bryan Roberts on more biological systems.⁴ My last studies were on dynamic systems with proton exchange⁵ and systems containing oxygen as well as nitrogen, including nitrites, nitrates, and nitroso compounds.⁶ The examination of nitrosobenzene was inspired by Rex Richards's plot of ^{14}N chemical shifts versus the wavelength of the lowest energy electronic transition. The λ_{max} of nitrosobenzene at 755 nm suggested a really low field chemical shift, which by synthesis was realized at δ 913, still possibly the low field ^{15}N extreme.⁶ I had made one valiant effort to observe ^{15}N at natural abundance, using 90% nitric acid, without success. Natural abundance observations had to await the new generation of spectrometers in the late 1960s based on frequency sweep and finally became routine in the 1970s with Fourier transform systems.

Research specialties: conformational analysis, reaction mechanisms, main group chemistry, electronic interactions.

Laszlo, Pierre: Getting Acquainted with a Spin-3/2 Nucleus

Pierre Laszlo

Université de Liège, Liège, Belgium; Ecole Polytechnique, Palaiseau, France

‘Nobody can ever speak for anybody but himself—and even then in doubt and great confusion’

Gavin Ewart, ‘No Fool Like an Old Fool’, Gollancz, London, 1976, p. 71.

I received a call from the University of Liège and moved there from Princeton in 1970. There was an old Varian HA-100 machine, but shortly thereafter, the university acquired a Bruker HFX-90 Fourier transform spectrometer. For our ‘Organic Spectroscopy’ book, published in 1970, Peter Stang and I had obtained from David Grant a few early carbon-13 spectra. They had made me familiar with ^{13}C NMR. For a couple of years we sheepishly stayed on that bandwagon. At the University of Liège, regardless of expertise, NMR was firmly in the hands of the physicists. Professeur Henri Brasseur, who had been entrusted with the purchase of the new spectrometer, was an X-ray crystallographer. An on-going collaboration with Pierre Tarte, a silicate chemist, made him equip the HFX-90 with a sodium-23 probe and channel. These had never been used. At some point, because of the above-mentioned turf war—these are endemic in universities, who are we to blame the Yugoslavs!—in which I had willy-nilly become embroiled, I made a snap decision to blitzkrieg the sodium-23 territory. A brainstorming session with my co-workers defined the exploratory experiments we would do. We had no more than two months, we felt, to acquire competence and make a successful contribution, visible enough to ensure local respect.

The literature, besides showing us Paul Lauterbur’s footsteps—he did pioneering work in this area as in so many others—showed a range of chemical shifts of some 40–100 ppm after preparation of the sodium anion by J. L. Dye.¹ We also found that a sodium chloride external reference in a capillary would do, with a small correction for the difference in magnetic susceptibilities. After a few years of work, our bibliographical equipment was markedly improved, if indirectly, by a copy of Lindman and Forsén’s book on halide ion NMR.² It told us all we needed to know about quadrupolar nuclei with nonintegral spin numbers.

A graduate student, Christian Detellier, had spent several years working on the ion-paired systems formed by iodine and triphenylarsine in organic solvents, much complicated by formation of polyiodides. Overnight we switched his attention to sodium salts, dissolved in ether and polyether solvents. Our goals were to define solvation numbers for Na^+ , to determine equilibrium constants for complex formation with such coordinating ligands, as well as with the then relatively novel crown ethers and cryptands. From the start, perfectionism and a desire to achieve as full an understanding as feasible gave us the following imperatives: not to content

ourselves with empirical correlations between the chemical shift and the desired parameters—relaxation rates were equally important: basing our conclusions firmly on consideration of both observables; and, in order to extract reliable kinetic and thermodynamic parameters from the data, making accurate computer simulations.³ Solvation and ion pairing could thus be studied both in inorganic and in bioinorganic systems.⁴

Our reliance upon joint consideration of linewidths and chemical shifts made us realize that the two types of observables were intimately related. This made us resurrect Deverell’s outstanding electronic distortion model.^{5,6} This last contribution capped a couple of years of an exemplary collaboration as three close friends, of Freddy Delville, a mathematician, André Gerstmans, a chemical technician, and the aforementioned Christian Detellier.

At the onset of our ^{23}Na work, we shied away from studies of binding to large biomolecules. Our timidity found support in reports that univalent ions, such as sodium cations, associated only weakly to them and did not stay very long in the married state. A single sentence will serve to convey the stale flavor of the field at the time: ‘Because of short lifetimes of the macromolecular complexes of sodium, the relaxation rate of ^{23}Na cannot be used in studies of macromolecular dynamics in solution’.⁷ There are now whole papers devoted to precisely such studies!^{8–11}

The next step was to look at pieces of meat—my then wife, a physician, had suggested this to me in the early 1960s, and I had then told her that only a broad featureless absorption would result! The ^{23}Na resonance in biological tissue was peculiarly non-Lorentzian. It consisted of two overlapping lines, a narrow one superimposed on a broader one. The immediate temptation was to deconvolute: one would invariably find 40% of the narrow component and 60% of the other. Accordingly, quite a few people, following the intrepid and uncritical lead from Freeman Cope¹² rushed into print the conclusion of the coexistence of 40% sodium ions in the free state and of 60% in a bound state, affixed to biological macromolecules. Bob Hirst, then at Goodyear in Akron, whom I knew from our joint time at Princeton and from our common delight in a rather arcane 19th century book of exploration, ‘Voyage au Pays des Mormons’, saved my neck: he knew the literature. Indeed, the two $[\pm\frac{3}{2}, \pm\frac{1}{2}]$ and $[\pm\frac{1}{2}, -\frac{1}{2}]$ transitions, corresponding to the broad and the narrow component lines, respectively, differ in their spectral densities. Thus, each submagnetization has its intrinsic relaxation rate outside of extreme narrowing.¹³

Various experimental approaches, such as the measurement of the dispersion of the relaxation rates at various Larmor frequencies, allowed accurate determination of the spectral densities and of the attendant correlation times. In this manner, sodium ions with an ionic radius identical to that of the divalent calcium ions could be used (sheep in wolves’ garb) to explore calcium binding sites on biomolecules. Using this approach, Jean Grandjean and I studied a series of calcium-binding proteins.¹⁴ A fringe benefit was utilization of the observed correlation time, in favorable instances when the residence time of sodium on the protein was of the same order as the reorientational correlation time of the complex,¹⁵ to determine the full binding kinetics and thermodynamics. I was even able to convince a senior co-worker, André Cornélis, a staunch synthetic organic chemist to go on an NMR excursion, from which we brought back information about the ion-conducting membrane channels formed by gramicidin A.¹⁶

Our main effort, however, was directed to the formidable problem posed by the self-assembly of the 5'-GMP nucleotide, an all-important biological process since the G-rich regions of DNA are responsible for the pairing of chromosomes during meiosis as Felix Gilbert at Harvard was later to show. ²³Na NMR was an important asset in establishing some of the main feature of this structures held by noncovalent bonds only.^{17,18}

We had learned a lot, and not only about NMR of quadrupolar nuclei. To operate in commando manner and stake out a new field, to ignore dogmatic statements, to choose our own way far from the madding crowd, and to experience the delight of discovery. When the President of Liège University, Professor Betz, had the guts to award to us alone a new superconducting magnet spectrometer, rather than to a competing group of half-a-dozen fellow chemists, when he thus chose competence over politics, we felt totally vindicated in having gone it alone.

Biographical Sketch

P. Laszlo. b 1938. B.S., 1961, D.Sc., 1965, University of Paris, Sorbonne. Self-taught in NMR from Pople-Schneider-Bernstein and the Abragam lectures at Collège de France, 1961-62. Postdoctoral research, Princeton University, 1962-63. Assistant Professor, Princeton University, 1966-70; Professor, University of Liège, 1970-present; Professor, Ecole Polytechnique, 1986-present. Taught NMR courses at Hamburg, Cornell University, and University of Kansas, and NMR workshops in Europe, the United States, and Japan. Approx. 200 publications and among 14 books, 'Organic Spectroscopy' with Peter Stang in 1970 and editing of 'NMR in Newly Accessible Nuclei' (two volumes) in 1983. Current research specialty: NMR studies of molecular interactions and motions in chemical and biochemical systems.

Lauterbur, Paul C.: One Path out of Many—How MRI Actually Began

Paul C. Lauterbur

University of Illinois, Urbana, IL, USA

The invention of NMR imaging (MRI) can be traced back through a variety of specific incidents to a set of underlying interests developed in my childhood. This pathway does not represent the only route to the final result; many others would have converged to the same eventual result from other initial conditions, but this history does show that it is often impossible to predict the hidden ideas to be revealed at the end of a research journey. Knowledge of what we do not know is the beginning of wisdom. The story of what actually happened is told below.

Two particular ideas that were woven together during precollege days survived, with a little stimulus from science fiction, to become sources of future research activities: biology and organosilicon chemistry. Could there be a biology based wholly or partly on silicon, instead of or in addition to carbon? Those interests, led me, after graduation with a B.S. in chemistry from the Case Institute of Technology, to take a job with a Dow Corning-supported group at the Mellon Institute that synthesized and tested organosilicon compounds and polymers. Although I was unsure about graduate work, it was possible to study for a Ph.D. at the University of Pittsburgh without paying tuition, so that with a little extra effort I could have it all, as I straddled the worlds of industry and academia. Three especially seminal events occurred in those first years. Two of them came about because I was working on silicone elastomers, trying to understand cross-linking reactions involving Si–H groups and also the sources of the ‘filler effect’, the strengthening of silicone rubber by small particles (such as fused silica, strangely enough the equivalent of carbon black in carbon-based rubbers). The first question, the mechanism of the cross-linking reaction, led again to the question of free radical participation, sparking my interest in the recently discovered electron spin resonance method for detecting unpaired electrons. The second question also led to magnetic resonance, this time of the nuclear variety, through my interest in the physics of rubber elasticity and how particles interacting noncovalently with polymer chains could have drastic effects on the elastic modules, tear resistance, etc., of rubber. A paper on NMR relaxation times in such systems was published just then, and I gave a physical chemistry seminar on it at Pitt.

The third intrusion of magnetic resonance on my consciousness during 1952–53 was a seminar by Herbert Gutowsky, of the University of Illinois, on the proton NMR chemical shifts of substituted methanes and their use to deduce electron densities. Here at last was the ideal tool with which to develop clear insights into the difference between silicon and carbon chemistry! I proposed to Gutowsky that I would send him samples of a variety of substituted silanes (not readily available commercially) and that he and I would then try to work out what the comparative NMR data meant. He agreed.

It was the time of the Korean War, however, and my deferments ran out. I was drafted and eventually ended up at the Army Chemical Center, where my ‘experience’ with NMR got me a transfer and assignment to help set up the Varian NMR machine (40 MHz proton and ^{19}F , 17 MHz ^{31}P) which they purchased to support chemical warfare research. There I actually learned something about NMR and even published a few papers. After Army service two options developed: go to Illinois as a graduate student with Gutowsky, or persuade the Mellon Institute to buy an NMR spectrometer. The Institute itself declined, but the Dow Corning group took the plunge, at least partly because I claimed that useful ^{29}Si spectra would be possible. I chose that option, visited Varian and confirmed that ^{29}Si spectra could be seen (with an 8.5 Mc s^{-1} rf unit) and immediately decided that ^{13}C would be even more interesting. I soon published the first paper on ^{13}C NMR spectra.¹ The rest is another branch of personal and scientific history, except that ^{13}C led to interest in spin decoupling and biological polymers, which were both to become essential links in the chain of events leading to ‘zeugmatography’, as I originally called magnetic resonance imaging. Before that, however, I carried out research on NMR spectroscopy of a number of elements and on several outstanding questions in the field, and then completed a Ph.D. thesis on applications of ^{13}C NMR spectroscopy to studies of the electronic structures of molecules. When the industry-supported group at Mellon Institute began to seem too restrictive an environment, I accepted a faculty position in the Department of Chemistry at the new State University of New York at Stony Brook.

Two of the areas that began to interest me at Stony Brook led toward imaging. One was computer-aided acquisition and processing of spectra, and the other was biological applications. In pursuit of the latter I went to Stanford for a 1969–70 sabbatical, associated with John Baldeschweiler’s group in chemistry, but also working with a Medical Center laboratory on ^{13}C labeling of proteins, and with Syntex on tritium NMR. For the latter we borrowed a retuned 100 MHz rf unit from Varian and found that we could see the tritium signals from labeled steroids (one turned out to be labeled in an unexpected location) and I later helped set up a National Institutes of Health (NIH) Research Resource for such work at Stony Brook. The other project generated the first ^{13}C NMR spectrum of a protein, from work with LeRoy Johnson on an early superconducting spectrometer at Varian,² but the more ambitious projects with ^{13}C labeled proteins were still incomplete at the end of the sabbatical year. Nevertheless, I was well on my way to developing a program for using isotopic labeling to study proteins, and getting excited about the other opportunities in biology.

A funny thing happened, however, as I did more preliminary work and tried to get some grant support, which was certainly delayed because of the incomplete preliminary protein-labeling experiments at Stanford. I had helped a small company to get started, during my Mellon Institute days, to build spin decouplers for double resonance experiments, after Varian had discontinued their production just when I desperately needed one for ^{13}C spectroscopy. When that company decided to start making superconducting NMR spectrometers I arranged to buy one for biopolymer work, including a plan to study enzymes by replacing calcium with cadmium. Then, in May 1971, events accelerated. At a hastily called board meeting it was revealed that the company’s financial condition was not what the board,

the bank, the investors, and the customers had been led to believe. The banker threatened to throw the company into bankruptcy and close it down that day unless someone could be found to take over the company while an attempt was made to turn it around. Classes were over, I faced a summer without a grant or summer salary, and my superconducting system might never be finished if I didn't do something. Despite the need to commute to western Pennsylvania from Long Island, I agreed to take on the job.

There is a book to be written about that summer, but for present purposes the important event was a visit by a postdoc, Leon Saryan, from Don Hollis's laboratory at Johns Hopkins to attempt to follow up the studies reported earlier that year by Damadian³ on water T_1 and T_2 in tumor tissues. The possibility of observing interactions of water with living tissues had attracted occasional investigators over the years. Perhaps the most indefatigable of these was Odeblad,⁴ who was fascinated by the opportunities for characterizing the properties of human cells and secretions, and by the technical problems of observing NMR signals from small biological samples. Other early investigations included those on blood flow by Singer⁵ and studies of muscle by Bratton and co-workers.⁶ A remarkable anticipation of later research is to be found in an unpublished thesis by Ligon,⁷ who measured NMR relaxation times in the arms of living human subjects. The first NMR signals from entire living animals were published shortly thereafter by Jackson and Langham⁸ in 1968. A surge of interest in such studies became evident in 1971 when several papers on muscle appeared,^{9–11} but the attention of the medical community was first attracted by the report of Damadian that some animal tumors have remarkably long water proton NMR relaxation times.³

Efforts to reproduce these results and to explore their significance were soon underway in other laboratories,¹² but it was the measurements, referred to above, that I observed Saryan carrying out in September 1971 that caught my attention.¹³ Damadian's measurements had been done on the company's demonstration pulsed NMR spectrometer earlier that year, but I had not paid much attention, thinking that the controls were inadequate and the publicity overdone. The Hopkins studies were another matter, however. I watched them being done, including the sacrifice of the rats, specimen dissection, and the NMR measurements and was struck by the consistent differences obtained among various normal and malignant tissues. I knew, however, that biopsies were commonly done and examined by histologists, and I believed that NMR relaxation time measurements on tissue specimens were unlikely to contribute much to the rich variety of information available from optical microscopy.

All of this information about the tissues was apparently there, however, within the living organism. Was there any way that one could tell exactly which location an NMR signal was coming from within a complex object? That same evening I realized that inhomogeneous magnetic fields labeled signals according to their spatial coordinates, and made a leap of faith to the conclusion that the information could be recovered in the form of pictures (we would now say that the inverse problem could be solved). I was so sure of this that I immediately went out and bought a notebook and had the idea witnessed.

Why was I so certain? I remembered from my graduate student work that iterative solutions could be found for otherwise intractable problems using continuous functions

represented by a grid or network of points, and I knew that there were already so-called 'shim' controls on NMR spectrometers that could shape the static magnetic field in known ways, allowing in principle a solution to the problem in the form of an image constructed from one-center harmonic representations. However, a much simpler idea came to me during the next several days. Sets of linear gradients oriented in different directions could uniquely encode each of a finite number of points representing the object, and I thought that an iterative comparison of the 'projections' thus generated with those from images, progressively refined to minimize the differences, could converge on a correct solution. Mathematicians and computer scientists whom I consulted disagreed on whether it would work, so I just went ahead and calculated some simple examples by hand, finding that the method worked easily and well. Only after that had been done was my attention called to a report by Gordon and Herman¹⁴ containing an essentially identical algorithm for 'reconstruction from projections'. As I also discovered later, Hounsfield was bringing computerized axial tomography from X-rays (CAT scanning) to practical usefulness at about the same time.¹⁵

While working out the mathematics I asked myself two other important questions: would there be enough water proton signal-to-noise ratio for large objects in low magnetic fields to support useful resolution in practical acquisition times, and could large magnets with good enough homogeneity be built? The answer to the first question was easily calculated from equations in Abragam's standard book on nuclear magnetism. Those simple calculations revealed that physics allowed an adequate signal-to-noise ratio, and I had confidence that whatever physics allowed engineers could achieve. Next, there were examples of fairly large resistive magnets with fairly uniform fields in the literature, but more importantly there were also papers describing how to design them. It looked quite easy (and was), so almost everything had fallen into place to justify my instant faith that I had stumbled across an idea that was worth spending most of my time on for the foreseeable future, instead of carrying on with molecular structure studies.

The word 'almost' above is because I still did not know exactly *how* it would be useful in medicine to have a method for making three-dimensional pictures of the body, since I knew nothing about medical science or clinical practice. I therefore went to the new medical library at Stony Brook, skimmed innumerable books and journals on radiology, nuclear medicine, cardiology, oncology, and related subjects, and picked up the vocabulary I needed in order to talk to physicians. Very soon everything had fallen into place and I decided that I more-or-less knew what I was doing. After failing to convince various people and institutions that it was a good enough idea to patent, I started doing experiments, writing papers, preparing grant proposals (mostly rejected), and giving talks, starting in 1972 at Stony Brook and Brookhaven and at an American Physical Society meeting in January 1973. My first paper on this subject was published in *Nature* in early 1973.¹⁶

So that is how biology and silicon, simple mathematical techniques, a broad knowledge of NMR, the design of NMR shim coils, experiments on cancer tissue, the collapse of a small instrument company, and general contrariness threw up a new and unprecedented technique for medical and other imaging. I have left out many things that could have, but to

Figure 1 T_1 images showing the growth of an implanted tumor over a period of 38 days in a single mouse. Each two-dimensional picture, reconstructed from 12 projections, represents a thick section (ca. 3–4 cm) determined by the sensitivity profile of the rf coil

the best of my knowledge did not, influenced my conception of NMR imaging because I did not initially know about them. These include the NMR work of Gabillard,¹⁷ the one-dimensional NMR experiments of Fairbank and others on ^3He ,¹⁸ and a speculative patent application by Damadian.¹⁹ Only later did I become aware of much of the relevant mathematical literature, including a then little-known paper by Radon,²⁰ work by Bracewell^{21,22} and Cormack,^{23,24} and related ideas in medical imaging by Kuhl and Edwards,²⁵ in electron microscopy by DeRosier and Klug,²⁶ and the papers by Ramachandran.^{27,28}

In my laboratory at Stony Brook, we soon set out to apply the imaging method to the study of living organisms. The first animal imaged, in the 5-mm space then available, was a 4-mm clam. An image showing the soft body of the clam within its shell was reconstructed from four projections.²⁹ When a larger standard spectrometer could be suitably modified, it became possible to make images of a variety of objects up to 3 cm in diameter, including a living mouse.³⁰ Those experiments led to the first attempts to image malignant tumors in living animals. These continued, with gradual refinement of the techniques, during the following 2 years. A special

technique for the measurement of the spin-lattice relaxation time T_1 was worked out, using an intermittent CW scan. After calibration with known samples, and rather elaborate corrections for nonlinearities in the gradients, we reconstructed color images to show the growth of an implanted mouse tumor over weeks (see Figure 1). Thus, it was beginning to seem plausible that at least some cancers should be detectable by NMR imaging techniques in human patients.

Meanwhile, other publications on NMR imaging, beginning with the work of Mansfield and Grannell,³¹ had started to appear.^{32–40} Investigations on humans began,^{41–43} and further studies of animal tumors were carried out.^{37–44} In our own laboratory, work proceeded on a number of technical and medical aspects of NMR imaging. Chemical shift imaging of proton signals was described in 1975,⁴⁵ and paramagnetic contrast agents were introduced in 1978.⁴⁶ Three-dimensional projection reconstruction was largely developed between 1977 and 1981,^{47–50} and then applied and demonstrated in a number of applications.^{51–57} These included the first human breast imaging with a special breast coil,⁵² the first surface coil imaging,⁵³ rapid three-dimensional human head imaging,⁵⁴ and three-dimensional image display.⁵⁶ A human whole body

system for three-dimensional imaging was constructed,⁵² and studies of specimens removed during cancer surgery were carried out.^{55,57}

Most descriptions of the tangled processes of scientific discovery are cartoons, so oversimplified as to be useless for any purpose other than providing apparent evidence for preconceived notions, polemical disputes, and the justification of budgets. Here I have told a tale of work that was not *initially* socially responsible, guided by perceived national needs, or particularly accountable to superiors or sources of funding. It is a story of striving for the most interesting and significant goals that seemed to be accessible from a given point in space and time, considering the available facilities, knowledge, skills, and interest, and a flexibility of research agendas shaped by a belief that science is so strongly interconnected that it is usually not a good idea to butt one's head against a brick wall in the direct path to a goal when the general advance in knowledge and techniques is likely to allow it to be reached indirectly in due course. The exceptions are situations driven by specific military, medical, or commercial emergencies, but those thrusts use up inordinate amounts of resources, both human and financial, and are made possible only by the broad range of knowledge, skills, and experience developed in less frantic contexts, and by the unexpected breakthroughs that grow in the fertile soil of 'curiosity-driven' research (which might often be better described as 'opportunity driven'), the most cost-effective kind in the long run.

Paul C. Lauterbur. b 1929. B.S., 1951, Ph.D., 1962, Chemistry, University of Pittsburgh, USA. Research Associate, Mellon Institute, 1951–63. Faculty, State University of New York, Stony Brook, 1963–85. Professor, University of Illinois, 1985–present. NMR research includes: initial work in carbon-13, silicon-29 and other nuclei; conception and development of NMR imaging. Numerous awards in chemistry, physics, and biomedical sciences.

Led, Jens J.: Aspects of NMR Studies of Paramagnetic Metal Complexes of Biological Relevance. A Historical Sketch

Jens J. Led

University of Copenhagen, Copenhagen, Denmark

In the late 1960s and the early 1970s much attention was focused on the application of NMR to the study of paramagnetic metal complexes of biomacromolecules and biological systems, such as metalloenzyme–substrate systems. In those premultidimensional NMR days the dramatic and often specific effect on the NMR spectra, caused by the interaction of the observed nuclei with the unpaired metal electrons (see *Electron–Nuclear Hyperfine Interactions*), offered a unique method of extracting detailed information from the complex NMR spectra of such molecules and systems. This includes information about the structure, dynamics, and specific interactions of the biological systems, obtained from the changes of the relaxation and chemical shifts of the ligand nuclei. Excellent reviews by Mildvan and Cohn^{1,2} cover, through 1970, paramagnetic relaxation effects in biochemical molecules with particular emphasis on enzymatic mechanisms, while an equally thorough review³ by Phillips covers the influence of the paramagnetic metal ions on the chemical shifts of biomacromolecules.

The theoretical models for the paramagnetic relaxation (see *Paramagnetic Relaxation in Solution*) of the nuclei given by the Solomon–Bloembergen–Morgan (SBM) theories,^{4–6} are complex. This often makes a complete unraveling of the experimental data in terms of information about the structure and dynamics difficult, while the unraveling requires a considerable amount of experimental data. Because of this inherent difficulty, certain assumptions were often made as to the nature of the relaxation mechanisms involved, or to the magnitude of the associated parameters, in order to reduce the complexity of the interpretation and accommodate it to a limited amount of experimental data. Although this procedure could be justified in some cases, in others it led to clear inconsistencies between the experimental data and the applied model. Thus, both the time modulation and the magnitude of the zero-field splitting that cause the paramagnetic relaxation seemed incompatible with the SBM theories. Also the point-dipole approximation of these theories appeared to be violated. In most cases these inconsistencies were ascribed to deficiencies of the theoretical model rather than errors in the assumptions.

During a sabbatical leave from 1971 to 1973 that I spent in David Grant's laboratory at the University of Utah, we set out to investigate to what extent experimental NMR data of the paramagnetic Mn^{2+} and Ni^{2+} complexes of amino acids and nucleic acids can in fact be described by the SBM theories

for relaxation if a data set is applied that is sufficiently large to allow an independent determination of all the parameters involved. The amount of data necessary for this analysis was substantial and included R_1 and R_2 relaxation rates and chemical shifts obtained at two magnetic field strengths and covering a wide temperature range. The observed nuclei were ^{13}C and ^{31}P . These nuclei were chosen because of their large chemical shift dispersions and because they allow a simpler theoretical model to be applied.

The result of the analysis was encouraging. Thus we found that the relaxation of the ^{13}C and ^{31}P nuclei in a series of representative binary and ternary Mn^{2+} - and Ni^{2+} -complexes^{7–9} of amino acids and nucleic acids conforms closely to the SBM theories for the nuclei and electron relaxations, and that the parameters obtained were in general accord with the basic assumption of the theories.

Further development in the application of paramagnetic metal ions in the studies of biological systems was made by the establishment of the activity of the Mn^{2+} derivative of carbonic anhydrase^{10,11} (see *Carbonic Anhydrase*) in the catalysis of the reversible $\text{CO}_2/\text{HCO}_3^-$ hydration-dehydration reaction, $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HCO}_3^- + \text{H}^+$, and the experimental verification of the central pentacoordinated metal complex in the catalytic pathway previously suggested by Lindskog. These results were achieved by a combined measurement of the paramagnetic relaxation and chemical exchange of the ^{13}C nuclei in the two substrates, CO_2 and HCO_3^- , in a magnetization transfer experiment (see *Enzyme-Catalyzed Exchange: Magnetization Transfer Measurements*). A central issue in this study was the use of sets of *complementary* magnetization transfer experiments, as shown in Figure 1. Thus it was demonstrated, both theoretically and experimentally, that only by using such sets of experiments was it possible to achieve an amount of experimental information sufficiently large to allow an independent determination of the three involved rate constants, i.e. the R_1 relaxation rates of ^{13}C in the two sites, and the rate constant for the catalytic exchange between these sites.

Lemieux, Raymond U.: First Observations: The Dependence on Torsion Angle of the Magnitude of the Coupling Constant for Vicinal Hydrogens and its Sign Compared to that for Geminal Hydrogens

Raymond U. Lemieux

University of Alberta, Edmonton, Alberta, Canada

While visiting the National Research Council of Canada (NRC) soon after I had moved to the University of Ottawa in the summer of 1954, I learned from my colleagues in organic chemistry that there existed a new spectroscopic method, based on the magnetic moment of the hydrogen nucleus, that allowed a nondestructive determination of the hydrogen content of an organic compound. This was highly intriguing. A few months later I returned to attend a physicist's lecture on the chemical shifts of the hydrogen atoms in fused-ring aromatic systems (published in 1957¹). My attendance was strictly curiosity-driven. Little did I realize that I was about to gain the privilege of participating in the development of a revolutionary force for the advancement of chemical knowledge. This good fortune came to me because of my close proximity to NRC, which had recently acquired one of the very first Varian Associates HR-40 NMR spectrometers, and the expertise that was brought to a collaboration which I established with leaders in the still budding field of NMR spectroscopy, namely, Bill Schneider and Harold Bernstein.²

In his lecture, Chris Reid¹ demonstrated that chemically similar hydrogens in fused-ring aromatic molecules were chemically shifted when their immediate environments were different. This finding caused me to wonder whether or not NMR would also differentiate chemically similar hydrogens that differed in their environments because of their orientation on six-membered rings; that is, whether the orientation was axial or equatorial. It was on the basis of this idea that I approached my friends at NRC. The generous access to the machine and the expert guidance they provided to my Ph.D. student, Rudolf Kullnig, led to a joint communication in 1957 entitled: 'Configurational Effects in the Proton Magnetic Resonance Spectra of Acetylated Carbohydrates'.³ The details and further observations were reported in the following year.⁴ This latter paper became a Citation Classic.⁵

As hoped for, differences in chemical shift occurred and it turned out that an equatorial hydrogen normally produced a signal at substantially lower field than a 'chemically equivalent' hydrogen in axial orientation. On its own, this was a truly exciting discovery. However, with the improvement brought to the NMR experiments by spinning the sample tube and using a superstabilizer, the signal-to-noise ratio was

increased to the extent that it could be concluded that the magnitude of a coupling constant for vicinal hydrogens was three- to four-times larger when the relationship was antiperiplanar than when it was synclinal. This was a true discovery, in the sense that it had not been anticipated by theoreticians, that has received an enormous number of applications starting with our paper entitled 'The Configuration of 3-Methoxycyclohexene Oxides. A Novel Application of Proton Magnetic Resonance Spectroscopy for the Determination of Structure and Configuration'.⁶ The Karplus equation⁷ for relating the torsion angle of vicinal hydrogens to the magnitude of their coupling constant together with Eliel's expression⁸ for interpreting time-averaged chemical shifts and, soon thereafter, time-averaged coupling constants in terms of conformational equilibria, opened many new avenues for research, especially since the tenets of conformational analysis as developed by Barton⁹ were firmly in place. My chief personal reward was that NMR allowed an unequivocal proof for the existence of a stereoelectronic contribution to bond strength which I termed the anomeric effect and which has since found widespread application. In fact, it was a preoccupation with the puzzle posed by the anomeric effect that caused my early involvement with NMR.^{10a}

Since the requirements for a meaningful examination of the conformational equilibria for five-membered ring compounds appeared available, we undertook a study of the conformational properties of monosubstituted 1,3-dioxolanes.¹¹ These compounds were chosen because only three hydrogens are coupled to each other; namely, a pair of geminal hydrogens that is vicinal to a single hydrogen atom. Bob Fraser's initial attempts to establish the values for three positive coupling constants for the ABC-type system did not produce acceptable simulations of the observed spectra. However, fine simulations were achieved when the geminal coupling constant was made negative.¹² The *Journal of Chemical Physics* refused to publish our report presumably because our conclusions were contrary to published theoretical expectations. My colleague, Frank Anet, established that it is in fact the geminal coupling constant that has the negative sign.¹³

The subjects of this article are reviewed in greater detail in my autobiography published by the American Chemical Society in 1990.^{10b}

Levitt, Malcolm H.: A Cyclic Evolution In Spin Space

Malcolm H. Levitt

University of Stockholm, Stockholm, Sweden

I was recently on a boat in central Finland, and was impressed by the complex topology of the waterways. Wide island-studded lakes are joined by narrow channels, leading by circuitous detours, sometimes back to the starting point, sometimes to new vistas. Contemplating this article, I was struck with the analogy to my experience of science. The conceptual space we traverse is unpredictable and complex. Even now, 50 years after the discovery of our particular lake, new channels still turn up, within earshot of familiar waters churned by water-skiers and tourists. Sometimes the channels are dead ends, sometimes they only return to the beginning, but in any case, the view always changes.

My research experience started in 1979 when I joined Ray Freeman's group in Oxford as an undergraduate 'Part II' student. I immediately found NMR much to my taste as a mathematical field with a human, geometrical, face. I would doodle endlessly with vector pictures of echo formation. Geoffrey Bodenhausen taught me to write pulse programs in octal machine code. I was awed by the control of radiofrequency fields by mere sequences of ones and zeros. Geoffrey interested me in a (forgotten) experiment based on a train of many π pulses. Perhaps fortuitously, that particular experiment proved impractical on our primitive 80 MHz instrument, since the radiofrequency field was very nonuniform. This made me think about a way of compensating the radiofrequency field distribution by some sort of echo. I soon came up with a self-compensating three-pulse sequence. To my surprise, the idea survived the scrutiny of Gareth Morris, the acknowledged guardian of scientific rigor in the group at the time. Ray Freeman, with inimitable knack, came up with a name, and the composite pulse was born.¹

Much of NMR can be interpreted in terms of rotations, so I had hit upon an idea with a bright future. For a long time I was to teach myself chunks of NMR purely by pushing composite pulses into some area. Ray Freeman stressed one particular line. He was intuitively convinced that the unsolved problem of broadband heteronuclear decoupling would eventually yield to the composite pulse, and never ceased pressing me to look into it. The breakthrough was Aue and Ernst's paper on J scaling.² This put the missing theoretical tools in my hands, and with some headscratching the first composite pulse broadband decoupling sequence was a reality.³ Demonstrating it, however, still required reams of octal machine code. I could not count beyond seven for weeks.

The next step was to generalize the construction principles. I came up with a scheme based on phase shifts and cyclic permutations.⁴ This was suggested by my experience as an electric guitarist in a jazz-fusion band, where we were using permutations to generate unusual musical effects. John Waugh had the same idea independently,⁵ presumably with a different source of inspiration.

After a spell in Shimon Vega's lab in Israel, I joined Richard Ernst's group. In this vital environment I soon gained experience in many different fields, such as composite pulses in solids⁶ and excitation of high-order multiple quantum coherences in liquids.⁷ I could witness important developments such as the invention of product operator techniques by Sørensen,⁸ and the treatment of phase cycling by Bodenhausen.⁹ At last I broke with my beloved rotations, and moved into an entirely different area: spin dynamics and thermodynamics in solids. By a trivial mistake in a pulse program, I hit upon a remarkable effect: synchronous phase switching of the spin locking fields in a cross-polarization experiment can compensate for Hartmann-Hahn mismatch.¹⁰ It took Dieter Suter and myself over two years before we even had a half explanation. I still consider the 'quasi-equilibrium' involved in this experiment as one of the biggest mysteries in routine NMR. Why does an apparently infinite spin system 'get stuck' in some nonequilibrium, nonuniform, polarization state? In my view there is much to be learnt here about the relationship of quantum mechanics to thermodynamics.

In 1985 I joined the Francis Bitter Magnet Laboratory in Cambridge, MA and collaborated closely with Bob Griffin and his group. My experience of cross polarization was useful for treating the interesting phenomenon of rotational resonance. Dan Raleigh had noticed a curious spectral broadening when doubly ^{13}C -labeled samples are spun in the magnet at just the right frequency.¹¹ This could be interpreted in terms of nuclear spin transitions induced by the sample rotation, suggesting the existence of rotation driven cross relaxation, and thereby a solid state analog of the nuclear Overhauser effect in liquids.¹² Rotationally resonant nuclear magnetization transfer is indeed gaining popularity as a method for determining molecular structures in the solid, or near-solid, state.

But with strange persistence, those simple sequences of π pulses keep coming back. Lorenzo Di Bari and I have been examining a curious *long-term* effect of π pulse trains. Like most, I would have expected that a long train of strong π pulses, lasting for many times T_1 , would eventually saturate the spin system, destroying all order. Nevertheless, we have now shown that in the presence of certain relaxation mechanisms, the π pulses can actually *generate* spin order, leading to a correlated spin configuration (two-spin order).¹³ This unusual effect is explained most easily by a reformulation of the 'master equation', striking at the heart of our usual conception of NMR experiments. It is characteristic of NMR that in the midst of well-traveled waters, we find an unexpected byway, leading in this author's case back to his very first experiences in scientific research.

Levy, George C.: Recollections: Computers in the Early Days of ^{13}C NMR and 25 Years of Growth in NMR Computing

George C. Levy

Infomatrix, Inc., Ann Arbor, MI, USA

1968–70

While there were major advances in experimental NMR between its discovery in the 1940s and the late 1960s, nothing prior to that time compared with the revolution afforded by the advent of pulse Fourier transform experiments and the availability of heteronuclei lock and broadband ^1H decoupling channels. It is hard for us today to remember the earliest days when David Grant, J. D. Roberts, and a few other pioneers needed *more than 1 g of a low molecular weight molecule* to get a ^{13}C NMR spectrum. Initial Fourier transform ^{13}C NMR experiments gained about a factor of 20 in sensitivity through rapid time averaging of free induction decays (FIDs).¹ Improvements in probe and receiver designs, and operation at ever higher magnetic fields, eventually extended NMR sensitivity such that today's ^{13}C NMR sample can be smaller than those used for ^1H NMR in the 1960s. There were many things we needed to learn back then, and a lot of tricks we used to make experiments work. To set the scene, let's describe the situation in most research NMR laboratories at the end of the 1960s.

Most NMR instruments of the time were based on electromagnets having field strengths as high as 2.3 T (100 MHz for ^1H or 25.1 MHz for ^{13}C). An attached computer was rare, and when present it was usually a hard-wired signal averager with little or no additional capability. Bruker and then Varian began to manufacture FT NMR instruments with dedicated programmable computers. At the time, I was at the General Electric Corporate Research and Development Laboratory in Schenectady. I had been hired to continue and expand upon early NMR research and services established by John Bush, who was heading into management (John later became Vice President of Research & Development at Gillette). I went shopping and selected the newly announced Varian XL-100, accepting delivery of the first FT XL-100 delivered in the USA. (For months after delivery my XL-100 was a continuous wave (CW) instrument and then Varian field-installed the FT accessories.)

The system computer was a Varian 620i computer with 16 384 16-bit words of core memory and a paper tape punch/reader on its Teletype user I/O device. There was no magnetic storage—disk or tape. Every time we had a glitch or (heavens!) software failure, the computer had to be reloaded by hand toggling a starter program and then loading several paper tapes at 110 baud (about 12 characters per second). The

very limited computer memory only allowed minimal NMR data acquisition and processing software, and only a single FID of 8k data points could be acquired and stored. In a few months we added an additional 16 kbyte stack of core memory at about \$0.70 per 16-bit word, over a *million times the cost* of much smaller and much faster modern memory chips. (At the time of this writing, single chip memories of up to 64 megabits—8 Megabytes—are available.)

Our spanking new FT NMR spectrometer was great, but there were a few surprises. For example, we were all held hostage to our plotter pens. Since the computer could not store more than the single spectrum being acquired, it was necessary to plot that spectrum before proceeding to acquire another. I was interested in applying ^{13}C and other nuclei spin relaxation measurements to obtain an understanding of molecular motions and interactions between groups, molecules, solvent, counterions, and so on. Typical ^{13}C inversion–recovery T_1 measurements could then be acquired in an hour or so, and a complete experiment (10–12 spectra with varying τ values) would go overnight. Unfortunately, two problems often arose: (1) If the spectrometer/computer amplitude settings and spectrum plot offset were not carefully set, some of the spectral peaks could go off-scale and not be measurable. (2) Even if all settings were O.K., the plotter liquid ink pen might clog and not show the spectrum. Varian used a 'woodpecker' routine to tap the pen on the paper and try to start ink flow. In retrospect, it is amazing that it took quite a while for most of us to realize that we could replace the whole pen assembly with a more reliable ball-point or fiber tip pen. On weekends, I beat a regular trail to and from the lab, to change experiments and plotter paper, if the pen had written.

Because most of our experiments required multiple plots, after a short time we bought a digital magnetic tape unit and interfaced it to the XL-100 computer. Charley Peters, our Varian engineer, modified the NMR program to support dumping spectra to the tape. Life was better after that.

During the next few years, we were able to learn much about anisotropic molecular tumbling,^{2,3} internal group motions,⁴ solvent-restricted molecular dynamics,⁵ and specific steric and electronic effects in largely rigid and inflexible molecules.⁶ Subsequent inclusion of ^{29}Si and ^{15}N spin relaxation studies provided insight into organosilicon and nitrogen-containing molecules.^{7–9} In the mid-1970s we discovered the potential of multifield ^{13}C spin relaxation measurements for learning about cooperative motions in micelles,¹⁰ synthetic polymers,¹¹ and DNA.¹²

1976

A great many changes took place in NMR instrument computers during the next half-decade. The newest systems had disk memories of a few megabytes and NMR data acquisition and processing software gained flexibility through the use of computers having more than 64 kbyte of random access memory (although most machines at that time still had a 64 kbyte address limitation, which was a challenge to the instrument company programmers, who had carefully to design program overlay structures). It was at this time that we realized that software provided by the instrument manufacturers limited some of the things we needed to do. Also, we wanted to be

able to process and analyze our NMR data offline, so as to maximize the throughput of the spectrometer.

At that time the spectrometer computers could only deal with one activity at a time, thus offline processing allowed the instrument to begin another experiment immediately, without losing time while the operator processed, examined, and plotted the latest experimental data. Finally, the NMR instrument computers of the mid-1970s did not support then-standard computing technologies: efficient floating point computation, large random access memories, good language compilers with program development tools, etc. Use of a 1977 general purpose minicomputer enabled us to have all of these capabilities, and supported two simultaneous users!

Thus was born the project to network our NMR laboratory, using microcomputers to acquire and transfer data, and a Data General Eclipse computer for centralized processing, plotting, archiving, etc. The 8-bit parallel computer network, developed by graduate student Dan Terpstra, was named WARPETH¹³ (Widespread Accurate Rapid Parallel Asynchronous Transfer Handler); the initial name for our one-dimensional NMR data processing software, developed by a team headed by then-student Charles Dumoulin, was ORACLE (Optimized Real-time Analysis for the Chemical Laboratory Environment). (After a while, we received a letter from a little-known database management company telling us that they had reserved the name ORACLE.) This software¹⁴ eventually became known as NMR1 (NMR2 was developed for two-dimensional NMR).

1982–85

By 1982, NMR1 had gained several capabilities that were not available in other processing software. The program was getting large and complex, and our ideas outstripped our ability to write and maintain code. With support and encouragement from the Syracuse University administration, we decided to form a company to develop and support enhanced, comprehensive software products for processing and analysis of NMR data. I remember well the day a few of us had a beer and pizza party in my living room to name the new company.

I said that the new company would some day develop software for methods other than NMR spectroscopy, so we shouldn't restrict the name by directly using the acronym for nuclear magnetic resonance. But I wanted to have easy name recognition for the company. My wife, Linda, came up with the answer: New Methods Research, Inc.; abbreviated NMRI.

NMRI went on to achieve a number of firsts, including the first demonstration and commercial offering of NMR software on workstation computers (Apollo and Sun, by 1984), network-style data transfers with file conversion to a published universal NMRI datafile format for NMR data from all of the instrument manufacturers, high-level 'smart' algorithms to replace most direct user manipulation of spectral phasing, etc., and a high degree of automation for tasks such as curve fitting complex, overlapped bands. Early on, we recognized the wisdom of using *standards*. In particular, we moved to the emerging X-windows graphics standard, years before Sun and other workstation companies fully supported X. This did present its share of problems, and it delayed our software releases more

than once, as we worked with the computer vendors to get X-windows working on their new systems.

1995

On the 50th anniversary of NMR, much is different in computer technology and NMR data processing. Personal computers have 1000-times the computing power of those 1970s NMR instrument computers; graphics workstations used for NMR processing are *more powerful* than Cray supercomputers, at a *thousandth* of the cost.

And the end is not in sight. By the year 2000, supercomputers will have yet another two orders of magnitude in speed; PCs may be comparable to today's fastest supercomputers. This may be used profitably. Tomorrow's multidimensional NMR datasets may contain 10^{10} data points. Totally automated data processing may include tasks that today require hours to weeks of careful analysis by spectroscopists. Automated preparation of accurate peak tables would support totally automated spectral assignment for a majority of molecules—including accurate assessment of three-dimensional structures.

We just have to wait a bit, but these things will happen before NMR spectroscopy gets past middle age.

NMR data processing and NMR laboratory networking software based on general purpose computers and workstations. Approximately 240 publications. Co-authored with Gordon Nelson the first published ^{13}C NMR book. Research specialties: ^{13}C NMR, data processing methods for one- and multidimensional NMR, utilization and commercialization of technology.

Lösche, Artur: The Beginnings of NMR in Leipzig

Artur Lösche

Formerly University of Leipzig, Leipzig, Germany

In the fall of 1940 I began my studies of physics at the University of Leipzig. Approximately a dozen years before, Pauli had suggested the existence of nuclear moments, a hypothesis to explain the hyperfine structure of spectral lines. It was the time when Rabi, Millman, and others observed the first transitions between nuclear Zeeman levels in molecular beams by resonance. Our physical discussions were dominated, however, by the experiments of Otto Hahn and Fritz Strassmann, and the possibilities of the fission of uranium by neutrons. In Leipzig, Heisenberg and Döpel prepared some investigations of this effect in bulk matter, which succeeded in 1942. At that time, however, I was far away as a consequence of World War II.

In 1945, when I came back, the Physical Institute was in a bad state (see *Pfeifer, Harry, Leipzig, Summer 1951*); 80% of the buildings were destroyed, the experimental equipment was deficient, and the supply of new information incomplete. Much work had to be done to reinstall education in fundamental physics. Some fields of research were forbidden by law of the Allied Forces (valid until about 1955). Research work in physics was not only a problem of new ideas, it was also determined by the reduced possibilities we could realize under such circumstances.

In 1949–50, I read in the *Physikalische Blätter* a paper by Braunbek entitled ‘Kerninduktion’ (nuclear induction), which was a report on experiments undertaken by Bloch, Purcell, and co-workers five years previously: transitions between nuclear Zeeman levels were observed in condensed matter. I became interested in this method, because a few months before I had some preliminary thoughts on how to demonstrate the rotation of molecules. Nuclear induction seemed to be a suitable method for us. This was promoted by the fact that none of us had had any experience with possible technical problems. By a fluke I took advantage of participation in a meeting of the Nordwestdeutsche Physikalische Gesellschaft in Münster and read the original papers by Bloch, Purcell, and others in *Physical Review*. Finally, in the summer of 1950, we had the opportunity to obtain the fundamental journals in physics from 1946 onwards and could satisfy our lack of information.

I proposed to some students that they should work in this field. One of them was Harry Pfeifer. He was the first in Leipzig to observe proton NMR signals in water with a superregenerative oscillator in the middle of 1951; his paper gives more details about his success. About the same time, Hans Lippmann and Karl-Heinz Weber explored the Bloch method with two coils perpendicular to each other and a twin T bridge, respectively.

Our first aim was to obtain some experience in experimental methods and in the theory of rf spectrometers. For this reason Horst Winkler, supported by Werner Helmert, looked for spin echoes which they found in 1954. Autodyne detectors were also used. In the spring of 1956 I had the opportunity

to report on our experimental results during the 5th Colloque AMPERE in Geneva.

In 1951–52, a small group of students at the Physical Institute of the Humboldt University in Berlin constructed a proton NMR spectrometer; Prof. F. X. Eder, the head of this institute, participated regularly in our seminars. After a short period, however, this work was stopped.

In the mid-1950s we began the next period, working in two directions:

(1) We tested additional methods, such as EPR and double resonance effects (Overhauser and ‘Underhauser’ effects, ENDOR spectroscopy and others). Furthermore, a magnetometer to measure the Earth’s magnetic field of the Packard Varian type was constructed and used for geophysical prospecting.

(2) We looked for possibilities of solving structural problems in liquids and solids using NMR parameters such as relaxation times, line shifts, splittings, and others. For this purpose it was necessary to separate these data from technical effects, e.g. field inhomogeneities and coupling between the spin system and the rf coil.

In our search for applications of NMR, we have tested since about 1956 a large field of physical phenomena, which can only be summarized here in a very brief way: the influence of different ions on proton relaxation in water, orientational behavior in liquid crystalline phases, special processes during the nematic–isotropic transition, structural phase transitions in ferroelectric crystals, polymerization process in epoxy resins, radiation damage in polymers, frequency shifts in semiconducting crystals, high-resolution NMR in organic compounds and in lyotropic phases, and the adsorption of molecules on solid surfaces. The results of these experiments on a trial basis are being expanded in today’s working groups.

It should be remembered that the first two decades of NMR were dominated by the CW technique with its limited sensitivity. As a result of this situation, I believed that the further development of NMR would be restricted. In my inaugural lecture during the 13th Colloque AMPERE in Louvain in 1964, I expressed the opinion that the NMR boom would finish in the near future. This proved to be quite wrong.

Since that time pulse and computer techniques have made great strides. A short time after that, fast Fourier transform spectroscopy was possible. This development from the CW technique to pulse spectroscopy with all its consequences was not only due to new physical knowledge but also to new technical possibilities. In general, I have the opinion that progress in science depends mainly on the cooperation of different disciplines.

Acknowledgements

I wish to thank Prof. Harry Pfeifer and Prof. Horst Winkler for helpful discussions.

Lowe, Irving J.: My Life in the Rotating Frame

Irving J. Lowe

University of Pittsburgh, Pittsburgh, PA, USA

PREAMBLE

I joined George Pake's magnetic resonance group in the Physics Department of Washington University (St. Louis) during the summer of 1952. I was attracted to magnetic resonance because of the tradition that experimentalists often did a lot of theory as well. Also, the happiest of my fellow graduate students were those working with Pake. Shortly thereafter Donald Maxwell, Erwin Hahn's first graduate student from Stanford, joined the Physics Department and I was assigned to help him design and build a pulsed NMR spectrometer. Don left after two years, before we had a chance to do much experimental work with the completed spectrometer. Pake had also gone, and I continued my research under the direction of Richard Norberg who had recently joined the Washington University Physics Department.

RIGID LATTICE LINESHAPES AND THE FT THEOREM

In February of 1956, I was busy measuring the free induction decay (FID) shapes, echo envelopes, and spin-spin, and spin-lattice relaxation times (T_2 and T_1) of fluorine in Teflon and protons in polyethylene samples as a function of temperature and manufacturing techniques. The purpose of the experiments was the measurement of the motion of the long polymer chains and of the percentages of amorphous and crystalline regions of the samples. My spectrometer was very primitive by today's standards, consisting of an incoherent pulsed oscillator as an rf source, a simple diode square-law detector (whose nonlinearities had to be corrected for) and a 0.68 T permanent magnet with a 1.9-cm air gap. Around the rf coil was a styrofoam cup for insulation and temperature control. The detected NMR signal was displayed on an oscilloscope face and photographed with a polaroid camera for data storage and measurement.

I had already taken many hundreds of photographs that would have to be digitized by reading the traces with a grid; the data then had to be corrected for nonlinearities, plotted, and analyzed. This was a tedious task that I had been putting off and which I wasn't looking forward to. I had one more set of experiments to do, that of measuring the FIDs of the rigid lattice of my polymer samples. To do this, one evening I poured liquid nitrogen into the styrofoam cup around the NMR coil and sample to cool them to 77 K where molecular motion is very slow. Much to my surprise, the FID I observed was not monotonic but displayed several 'beats' or oscillations. The liquid nitrogen boiled away in about 10 min and the sample began warming up; the FID got longer and the 'beats' disappeared and the FID was again monotonic. I measured

the FIDs of a number of other polymer samples at 77 K that evening and they all displayed a similar beat structure that disappeared as the sample warmed up. I was excited by these results, but was also bothered by them. I was well aware that Van Vleck¹ in his monumental paper on moments of NMR absorption lines had rigorously calculated the second and fourth moments (M_2 and M_4) for the rigid lattice case. He concluded that for $S = \frac{1}{2}$, for a set of equivalent spins in a cubic lattice that $[M_4/3M_2^2]^{1/4}$ was 0.95 for the applied magnetic field $\mathbf{B}_0$ along the [100] crystal axes, and about 0.99 for $\mathbf{B}_0$ along the [110] and [111] axes. This ratio is 1.0 for a Gaussian lineshape, and a Gaussian FID is monotonic and has no beats. Further, Pake and Purcell had measured M_2 and M_4 of ^{19}F in CaF_2 and obtained results² in good agreement with Van Vleck's calculations.

The next morning, I showed these peculiar results to Norberg, and to Pake who was visiting Washington University. They thought that the measurements were interesting and should be pursued. I was able to borrow a CaF_2 crystal from my classmate Bob Bruce, who was remeasuring M_2 and M_4 to obtain a more accurate value for them.³ The FIDs of ^{19}F in CaF_2 also displayed a similar 'beat' structure (as seen in Figure 1) at room temperature, and the 'beat' structure depended upon the orientation of the crystal axes relative to the magnetic field, $\mathbf{B}_0$. After photographing a set of FIDs for CaF_2 with $\mathbf{B}_0$ along the [100], [110], and [111] crystal axes, I turned off my spectrometer and started to calculate a formula for the general shape of FIDs for $I = \frac{1}{2}$ nuclei in a rigid lattice. Had I been less naive, I might not have attempted it, but I had the encouragement of Norberg and access to Henry Primakoff, a superb and helpful theoretician.

At that time, density matrices and time-ordered expansions were not popularly used in NMR calculations. In formulating the calculation of the FID shape $f(t)$, and then evaluating it, I developed my own version of each. Only after completing the calculations did I learn of density matrices from Primakoff and recast my calculations into that language without having to change any results. An important byproduct of these calculations was the suggestion and general proof of the theorem that the Fourier transformation of the shape function $g(\omega)$ of the NMR absorption lineshape was equal to the NMR free induction decay shape $f(t)$ to within a multiplying constant for solids, liquids, and gases for a completely general interacting Hamiltonian.

The calculation of $f(t)$ for any spin system starts with

$$f(t) = \frac{\text{Tr}\{\hat{I}_x(0)\hat{I}_x(t)\}}{\text{Tr}\{\hat{I}_x^2(0)\}} \quad (1)$$

where $\hat{I} = \sum_j \hat{I}_j$ is the total spin angular momentum operator, $\hat{I}_j$ the angular momentum operator for the j th nucleus, and

$$\hat{I}_x(t) = \exp\left(-i\frac{t\hat{\mathcal{H}}_{\text{DD}}}{\hbar}\right) \hat{I}_x(0) \exp\left(i\frac{t\hat{\mathcal{H}}_{\text{DD}}}{\hbar}\right) \quad (2)$$

where $\hat{\mathcal{H}}_{\text{DD}}$ is the truncated dipole-dipole interaction Hamiltonian

Figure 1 Free induction decay plots of ^{19}F in CaF_2 single crystals. (a) B_0 along the [100] crystal axis; (b) B_0 along the [110] crystal axis; (c) B_0 along the [111] crystal axis. Crosses indicate observed FID amplitudes. Circles show Fourier transform of Bob Bruce's data³ for the same crystal. The solid curve is the shape predicted by (65) in Ref. 5 (taken from Ref. 5)

$$\hat{\mathcal{H}}_{\text{DD}} = \hbar(\hat{\alpha} + \hat{\beta}); \quad \hat{\alpha} = \frac{1}{2\hbar} \sum_{j \neq k} A_{jk} \hat{\mathbf{I}}_j \cdot \hat{\mathbf{I}}_k;$$

$$\hat{\beta} = \frac{1}{2\hbar} \sum_{j \neq k} B_{jk} \hat{\mathbf{I}}_{jz} \hat{\mathbf{I}}_{kz} \quad (3)$$

$$B_{jk} = -3A_{jk} = -\frac{3}{2} \frac{\gamma^2 \hbar^2}{r_{jk}^3} (3 \cos^2 \theta_{jk} - 1) \quad (4)$$

where $\mathbf{r}_{jk}$ is the vector connecting the j th and k th nuclei, θ_{jk} is the angle $\mathbf{r}_{jk}$ makes with the magnetic field B_0 (which is in

the z direction), and γ is the magnetogyric ratio of the nuclear species. The quantity $\hat{\alpha}$ does not commute with $\hat{\beta}$ which made evaluation of equation (2) difficult. It does commute with $\hat{I}$ which means that it will only contribute to $f(t)$ through terms containing $[\hat{\alpha}, \hat{\beta}]$. The terms making up $\hat{\beta}$ all commute and were easy to evaluate exactly; indeed, evaluation of equation (1) for just the $\hat{\beta}$ terms showed a beat structure. I spent several more months evaluating terms dependent upon $[\hat{\alpha}, \hat{\beta}]$ and also Fourier transforming Bob Bruce's measured lineshapes for CaF_2 to compare with my measured FIDs. These results^{4,5} are also shown in Figure 1. The details of the calculations and theory are described in painful detail in my thesis⁴ and Ref. 5. I wrote my thesis over the summer of 1956 and never again opened the drawer containing all the hundreds of photographs of data on polyethylene and Teflon.

MAGIC ANGLE SPINNING AND RF NARROWING

In February of 1958, George Theiss, an undergraduate student at Washington University, started a senior project with me. I was still intrigued with lineshapes in solids, and thinking about motional narrowing in solids⁶ where the internal motion decreases the sample's observed NMR linewidth and apparent second moment M_2 . Van Vleck's¹ expression for the second moment M_2 predicted that it should be invariant to internal motions and rotations of the sample because the motional part of the Hamiltonian commuted with the total spin operator. The motional modulation of the resonance line certainly narrowed the observed lineshape but it should also produce sidebands which added to the wings of the line to keep M_2 constant. The motional contribution to the wings usually is too weak to be observed however, because the internal motion has a broad frequency spectrum and the sideband contribution to the wings has a broad frequency range. I reasoned that the NMR lineshape for a solid, rotating at angular speed ω_s , should show sharp sidebands at frequencies related to ω_s .

The Hamiltonian for the spin system is the same one listed in equation (3), except that when the sample is rotated at an angle θ_H with respect to B_0 , the addition theorem for Legendre polynomials yields the result

$$\begin{aligned} (3 \cos^2 \theta_{jk} - 1) &= \frac{1}{2} (3 \cos^2 \theta_H - 1) (3 \cos^2 \theta'_{jk} - 1) \\ &+ \frac{3}{2} \sin(2\theta_H) \sin 2\theta'_{jk} \cos(\phi'_{jk} - \omega_s t) \quad (5) \\ &+ \frac{3}{2} \sin^2 \theta_H \sin^2 \theta'_{jk} \cos[2(\phi'_k - \omega_s t)] \end{aligned}$$

where θ'_{jk} is the angle between $\mathbf{r}_{jk}$ and the axis of rotation. For $\theta_H = 0$, only the first term is nonzero and $f(t)$ is independent of the spinning speed of the sample. For $\theta_H = 90^\circ$, the first term becomes $-\frac{1}{2} (3 \cos^2 \theta'_{jk} - 1)$, and the partially narrowed line would then display the same shape as the nonrotating case but of one-half the linewidth and have sidebands at multiples of $2\omega_s$. For $\theta_H = \cos^{-1}(1/\sqrt{3}) \approx 54.7^\circ$, the first term vanishes, the line should fully narrow, and $g(\omega)$ would only have sidebands at multiples of ω_s .

With this theory in mind, George and I started working on a mechanical technique to rotate the sample fast enough

Figure 2 Free induction decays for spinning and nonspinning samples of powdered CaF_2 and their Fourier transforms (taken from Ref. 7)

to see these effects. We were unable to do so by the time he graduated in May, 1958. About then, I was having some dental work done and saw a new air turbine drill that my dentist used. I decided to try to spin the sample by blowing air past it. A gifted machinist (Jim Boyle) and I made up some NMR samples that were cylinders 7 mm wide, 7 mm in diameter, had nylon bearings, and spun on thin phosphor bronze wires as axles. I found that spinning speeds were limited only by the strength of the sample and that speeds up to 7 kHz were easily obtainable. I put the spinner into my NMR probe, found that I could narrow the line of both Teflon and CaF_2 , and was so excited that I worked for the next 48 hours taking data, stopping only when I had spun all my prepared samples to destruction. The next day, I woke up with a very high fever that was diagnosed as hepatitis a few days later when I turned a nice bright yellow. The dentist who was my source of inspiration for the spinning technique was also probably the source of my hepatitis infection. I was incapacitated for the next two and a half months, and two graduate students (Horst Kessemeier and Bill Yen) in the Norberg NMR group helped with analyzing the data of the FIDs and taking their Fourier transforms. The results⁷ in Figures 2 and 3 indeed show that

Figure 3 Free induction decays for spinning and nonspinning samples of Teflon and their Fourier transforms (taken from Ref. 7)

the spinning motion narrows the NMR lineshape and M_2 is seen to remain constant since the initial behavior of the FID is invariant to the rotation. Independently, and unknown to me, Andrew, Bradbury, and Eades⁸ also showed that spinning motion narrowed NMR lineshapes. The invariance of M_2 to internal rotational motion was demonstrated⁹ by my student, Ching Yao.

In 1962, I was at the University of Pittsburgh using a homemade phase coherent pulsed NMR spectrometer that boasted of linear-phase sensitive detection and several excitation pulses with adjustable phases. These luxuries allowed my students and me to study lineshape behavior and spin-lattice relaxation in the rotating frame.

For a spin system acted upon by a rotating magnetic field $\mathbf{B}_1$, rotating at angular speed ω , the effective magnetic field $\mathbf{B}_{\text{eff}}$ in the rotating coordinate system is

$$\mathbf{B}_{\text{eff}} = B_1 \mathbf{y} + \left(B_0 + \frac{\omega}{\gamma} \right) \mathbf{z} \quad (6)$$

where $\mathbf{y}$ and $\mathbf{z}$ are unit vectors in the y and z directions, respectively

By making a transformation to the coordinate system rotating about $\mathbf{B}_{\text{eff}}$ at angular speed $\omega_{\text{eff}} = \gamma B_{\text{eff}}$, one obtains a

new magnetic Hamiltonian whose time-independent terms are

$$\hat{\mathcal{H}}'_{\text{DD}} = \frac{1}{2}(3 \cos^2 \theta - 1) \left(\frac{1}{2} \sum_{j \neq k} B_{jk} \left(\hat{I}'_{jz} \hat{I}'_{kz} - \frac{1}{3} \hat{I}'_j \cdot \hat{I}'_k \right) \right) \quad (7)$$

where $\theta = \tan^{-1}(B_1/(B_0 + \omega/\gamma))$.

Equation (7) demonstrates that the time-independent terms vanish for $\theta = \cos^{-1}(1/\sqrt{3})$, the so-called magic angle. This is similar to the rotating sample technique described earlier. For $\theta = 90^\circ$, $\hat{\mathcal{H}}'_{\text{DD}}$ is just $-\frac{1}{2}\hat{\mathcal{H}}_{\text{DD}}$ and the FID should evolve at exactly one-half the rate as in the laboratory frame, as my student Dennis Barnaal and I demonstrated.¹⁰ At the same time, Walter Goldberg and Moses Lee, also at the University of Pittsburgh, demonstrated the magic angle case.¹¹

RELAXATION IN THE ROTATING FRAME

At about the same time, my student, David Look, and I were studying slow internal motions in solids and being frustrated by materials that would undergo phase transitions before reaching a T_1 minimum where their correlation time τ_c could be measured. We reasoned and then showed that for $B_1 \gg B_{\text{loc}}$ magnetization $M_y(t)$ that was spin-locked along a rotating

magnetic field B_{1y} would relax to zero in a fashion similar to $M_z(t)$ relaxing to its equilibrium value M_0 in the magnetic field B_0z . Since $B_1 \ll B_0$, the spin-locked magnetization relaxation rate, $T_{1\rho}$ would be much more sensitive to long τ_c values. We derived¹² a formula for $T_{1\rho}^{-1}$ whose dominant term in the long-time region is proportional to the spectral density function of $\hat{\mathcal{H}}_{\text{DD}}$ in equation (3), evaluated at $2\omega_1$. When evaluated for specific models of motion, the formula contains terms of the form $\tau_c/(1 + \omega_1^2 \tau_c^2)$. These formulas were tested¹² (see Figure 4) for T_1 and $T_{1\rho}$ in gypsum where the details of the flipping of the H_2O molecules are very well defined. Similar ideas for studying slow motions by measuring relaxation rates in the rotating frame were independently developed by Slichter and Ailion.^{13,14}

EPILOGUE

This article has described one limited but connected area of my work in NMR. Its imposed brevity has prevented me from referencing many of my other students and colleagues who have greatly influenced me. My years in magnetic resonance have been even more exciting and fun than I had imagined possible back in 1952.

Irving J. Lowe. b 1929. B.E.E., 1951, Cooper Union, Ph.D., 1956, Physics, Washington University (St. Louis). Thesis advisors were (in order) George Pake, Donald Maxwell, Richard Norberg. Sloan fellow at Washington, University 1956–58. University of Minnesota, 1958–62. University of Pittsburgh, 1962–present. Research specialties: NMR theory, solid state NMR, NMR instrumentation, magnetic resonance imaging.

Figure 4 Proton spin-lattice relaxation times in gypsum along the static and rotating magnetic fields as a function of inverse temperature. The quantity τ_c is calculated from the T_1 curve using Eq. 40 from Ref. 12. The computed activation energy is $5.8 \text{ kcal mol}^{-1}$. $\circ$ are T_1 data; $\blacktriangle$ are $T_{1\rho}$ data (taken from Ref. 12)

Lunazzi, Lodovico: Conformers and Enantiomers, Rotations and Stereomutations: an NMR Playground for an Organic Chemist

Lodovico Lunazzi

University of Bologna, Bologna, Italy

My love affair with NMR began more than 30 years ago in the fall of 1962. I was preparing my doctoral thesis in the lab of one of the most distinguished Italian organic chemists (Professor F. Montanari, now at the University of Milan) when the head of the institute (the late Professor Mangini) acquired one of the first high-resolution NMR spectrometers to be seen in Italy (a Varian DP-60). Along with the spectrometer, there came back to Italy a research associate (now Professor F. Taddei, University of Modena) who had spent some time in London, at University College and at Imperial College, learning how to use the new device. Fascinated by the results offered by this technique, I asked permission to modify my project and so had the privilege of being allowed to play with the new toy. Since then I have remained faithful to NMR and, subsequently, I even became addicted to its half-brother, ESR. The instruments of those times were not so easy to use as no lock was available and the spectrum had to be chased (and was sometimes lost) along a drifting magnetic field. Sidebands had to be employed for calibration and shimming had often to be performed by mechanically moving, with a gear, the poles of the magnet. So a simple ^1H spectrum required a few hours to be properly recorded: fortunately at that time Saturday was a full working day in our institute.

With Taddei, I applied NMR to measure the ^{13}C – ^1H coupling constants from the satellites of the proton signals in a variety of organic derivatives (some of them, like fluoroacetylene, were explosive and so dangerous to handle within the probe of the spectrometer that so far no one has measured these couplings again) and also learnt how to analyze second-order spectra. As no electrical computing devices were available, I did all the work with a mechanical one whose efficiency was determined by the rate at which I could rotate the handle (subsequently I was helped by a very muscular student who was able to rotate the handle even faster).

In 1967 I obtained a Canadian National Research Council (NRC) postdoctoral fellowship and moved to Ottawa to work with Syd Brownstein. There I became familiar with dynamic NMR as a tool to investigate exchange processes, a subject which is still one of my research interests: the series 'Conformational Studies by Dynamic NMR' which I started in 1972 has now reached its 50th paper. The work in Ottawa went quite well and the results of our investigation on the exchange kinetics between a carbonium ion and its parent molecule were eventually published in *J. Am. Chem. Soc.* in 1969. During that period I had the privilege of meeting Vladimir Bystrov,

a Russian physicist who was also undertaking postdoctoral work with Syd and who obtained worldwide recognition later for his NMR work on the conformation of peptides and natural biomolecules. We became very good personal friends and kept visiting each other in our labs in Moscow and Bologna over a period when it was not so easy for Russian scientists to have contact with foreigners. In addition to being an excellent scientist, Vladimir was a person of great thoughtfulness and humanity: his sudden, untimely death in 1989 has been mourned by all the NMR community.

In the NRC library I also came across a review by Geoffrey Luckhurst (whom I had already met in the Varian lab in Zürich) about the use of liquid crystalline solvents to obtain NMR spectra very different from those one is accustomed to observing in isotropic liquids. When I returned to Bologna I began to apply this technique to investigate the conformation of flexible organic molecules. At that time people were debating whether biphenyl, known to be planar in the solid and twisted in the gas phase, was planar or twisted in solution. By making use of a conveniently synthesized chloro derivative, we could convincingly demonstrate by NMR that the twisting angle was about 35° in a liquid crystalline solvent. The model I had employed for the analysis was quite approximate and was subsequently refined in joint work with Peter Diehl of the University of Basel. Many more examples were later published by Sternhell in *J. Am. Chem. Soc.*, nicely confirming the correctness of our results. I continued to investigate many simple flexible molecules by this method working with a postdoc from Milan (Giovanni Fronza) and with colleagues from Pisa (C. A. Veracini) and Southampton (J. W. Emsley). I had met Jim in 1971 at the ISMAR meeting in Israel and a NATO grant helped us to visit each other and publish many papers, together including those on two isomers of bipyridyl which were, for those times, a real 'tour de force' because of the complexity of the partially oriented 8-spin systems which had to be analyzed.

During my visits in England I also met Ed Randall, from Queen Mary College, London who persuaded me to write a chapter on the application of liquid crystal NMR (he suggested the acronyms LXNMR) for the sixth volume of the series 'Determination of Organic Structures by Physical Methods' he was editing for Academic Press. It was a lot of work but I do not regret it for, although it is now certainly outdated, it was quite useful at that time for newcomers in the field, particularly from a practical point of view. This task gave me the opportunity of benefiting from learned discussions with Claudio Zannoni, a student who was then doing his Ph.D. in Southampton with Geoffrey Luckhurst. He later became a colleague of mine in Bologna (as well as a close personal friend) and is now recognized worldwide as one of the leading experts of the liquid crystalline state.

Meanwhile I had the possibility of using a 100 MHz FT spectrometer with a good variable temperature device, which enabled me again to start investigations of dynamic processes. Fascinated by the pioneering work of F.A.L. Anet, I repeated, now using ^{13}C , his classical ^1H study on the restricted rotation of benzaldehyde. Later on, with the help of a very able technician, Dante Macciantelli, I studied the internal motions of a variety of simple organic molecules that, despite their fundamental importance, had not yet been investigated, probably because of the technical difficulties involved in reaching the required low temperatures (often ranges between

–120 °C and –160 °C were needed) in solution. Thus we measured accurate barriers for the rotation of *N*-methylaniline, isomeric pyridine and thiophene aldehydes, nitrosobenzene, phenylhydrazine, etc. These studies were pursued until quite recently when, using more sophisticated instrumentation, we could directly detect by ^{13}C NMR the amount of the minor conformer (as low as 0.8% at –140 °C) of furan-3-aldehyde. Some of these spectra were nice enough to be reproduced in a number of books, including that on ‘Dynamic NMR’ by Jan Sandström.

In 1975, with the help of a Sardinian post-doc (Gianni Cerioni), we enlarged our field of interest by studying more complex molecules exhibiting the so-called gear effect: we were even able to determine the first X-ray structure of one of the ‘gear conformers’ we had observed at low temperature by NMR.

Of course the more complex molecules we kept synthesizing exhibited a variety of internal motions, and in 1981 we were lucky enough to detect a quite unique feature in a molecule that, at –140 °C, exists in a coplanar as well as in an orthogonal conformation as shown in Scheme 1.

The different symmetries of these two species allowed their unambiguous identification by ^{13}C NMR and their relative ratio at equilibrium could even be reversed by an appropriate change of solvent.

In 1973 I again spent some time at NRC in Ottawa (this time in the lab of Keith Ingold to do some ESR experiments), and on his suggestion once back in Bologna I tackled the conformational analysis of the simple, fundamental hydrocarbon tetramethylethane. We were able to show that at –180 °C the *gauche* and *anti* conformers yield different ^{13}C spectra (the intensity ratio of the two forms being 2:1) and we could measure the corresponding interconversion barrier (4.1 kcal mol $^{-1}$). For this experiment I made use of the 360 MHz Bruker spectrometer in Fallanden, Switzerland (at that time the highest field available) and I still remember how frightened the technicians were when I forced the temperature of such a precious instrument down to –180 °C; they did not allow me to repeat the experiment a second time. The paper eventually appeared in *J. Am. Chem. Soc.* in 1977 and has always been a source of great satisfaction to me since it has been quoted even in stereochemistry textbooks.

The year 1983 marked the arrival in my lab of a young research associate, Daniele Casarini, with whom I started to investigate dynamic processes in chiral environments, thus making conformational enantiomers detectable by NMR. We observed, for instance, that the *N*-methyl ^1H signals of $\text{Me}_2\text{NCH}_2\text{Me}$ become anisochronous at –90 °C in the presence of a chiral agent, owing to the slow N-inversion process. The otherwise NMR invisible barrier could thus be measured by lineshape analysis. I still keep as a cherished souvenir the letter of Jean-Marie Lehn who congratulated us for this achievement. Again with Daniele (who had spent one year with Robin Harris in Durham to learn solid state NMR), I applied the CP MAS technique as a help for assigning *meso*

and racemic conformers, taking advantage of the symmetry breaking of the NMR patterns in the solid with respect to the solution. The results satisfactorily matched the corresponding X-ray findings.

Since 1986 I have also started a fruitful cooperation (with the help of a NATO grant) with Edgar Anderson of the University College, London. By combining MM calculations with dynamic NMR we studied a variety of internal motions in conformers of quite complex trialkylamines: we even detected as many as four different dynamic processes within a single molecule and measured the corresponding barriers. Once, to unravel a particularly complicated case, we had to resort to a 600 MHz spectrometer (installed in Florence by Ivano Bertini) where we recorded spectra down to –120 °C which was then one of the lowest temperatures attained for such a large magnetic field. This scientific cooperation with Edgar also gave rise to a long lasting friendship, which was subsequently shared by our wives and even by our children.

The activity in the NMR field enabled me to join people from all over the world in common projects and it is quite amusing that I could publish papers even before having met my foreign co-workers. This happened with a project I was pursuing in Bologna with a colleague of mine (Giuseppe Placucci): at a certain point in the work we wrote to a Japanese scientist (Renji Okazaki, University of Tokyo) whom we only knew from his papers, seeking a particular compound. Thus we started a common project (later also Gaku Yamamoto joined us) which was carried out by letter, telex, and eventually by fax. The results, concerning motional couplings in the rotational processes of a very hindered hydrocarbon, were obtained and discussed without a single personal meeting between the two groups. Only after publication in 1990 of our joint paper in the *J. Am. Chem. Soc.* did I meet Renji, with whom I have developed a very friendly personal relationship.

At the moment I am interested in studying conformational chirality in collaboration with a colleague from Rome (Francesco Gasparrini). Using dynamic NMR, we measure the lifetimes of conformational enantiomers and use this information to set up low-temperature chiral chromatographic columns that enable the physical separation of enantiomers which interconvert with barriers as low as 18 kcal mol $^{-1}$. It has even been possible to measure the corresponding circular dichroism spectra, thus assigning an absolute chiral configuration to these elusive species.

In conclusion, NMR keeps showing such a variety of useful and fascinating new aspects to the organic chemist as to seem an endless source of wonder: after more than 30 years I am not yet tired of playing with such a versatile toy.

Note added in proof: After completion of this short biography my beloved wife Anna died suddenly in November 1994. To her, who always helped, assisted and comforted me, this article is gratefully dedicated.

Lutz, Otto: Heteronuclear Magnetic Resonance

Otto Lutz

University of Tübingen, Tübingen, Germany

As a graduate student I had the chance to participate in the Nobel Laureate Meeting at Lindau (in the Bavarian part of Lake Constance) in 1962. One of the aims of the Lindau meetings was to promote contact between laureates and students. It was therefore deeply impressive to hold personal discussions with scientists whose work was well known from lectures and the literature. I would like to mention in this connection I. I. Rabi, E. M. Purcell and W. E. Lamb, who are seen together with H. Urey in the snapshot (Figure 1).

During this period I performed experiments on the lifetime of the excited atomic states of strontium using the optical-radiofrequency double resonance method. In 1963 I changed to the field of nuclear magnetic resonance. At that time the so-called less common nuclei or heteronuclei had not been investigated very well. For this reason, magnetic moments, chemical shifts, and linewidths were of great interest, especially since as a result of cooperation with Siegfried Penselin (Bonn) and Victor W. Cohen (Brookhaven) it was possible to evaluate absolute magnetic shielding constants for the alkali isotopes, for example.¹ This work was performed with a homemade spectrometer and probes and a Varian magnet externally stabilized at 1.8 T using a ^7Li NMR method introduced and implemented by Andreas Schwenk.² In the late 1960s and early 1970s a multitude of nuclei were investigated³ mainly in aqueous solution, especially when a Bruker B-Kr 322 s pulse spectrometer working in the Fourier mode replaced our homemade apparatus.

In 1975 we obtained a grant from the Deutsche Forschungsgemeinschaft with which to purchase our MONALISA, at that time an unusual combination of an externally stabilized 2.1-T Bruker SXP 4-100 pulse spectrometer and internally deuterium-stabilized high-resolution equipment (MONALISA was the solution of the problem of finding an appropriate girl's name which would fit as far as possible all the NMR-active

isotopes, reading forth and back: 15). With this spectrometer (which is still working!), together with lots of homemade probes for different frequencies and purposes, further less-sensitive nuclei could be observed⁴⁻⁶ and the list of observable isotopes could be expanded to more than 50.

During this period we started examinations of biologically interesting nuclei such as ^{25}Mg and ^{43}Ca ,⁷ and it was at the famous VIth International Conference on Magnetic Resonance in Biological Systems, Kandersteg, Switzerland, September 1974 when our cooperation with Peter Kroneck of Konstanz started, resulting in basic NMR studies on copper,⁸ vanadium,⁹ and molybdenum. The results on the latter element¹⁰ are still obviously of interest, as can be seen from a 1993 paper by Xie et al.¹¹ on the calculation of the ^{95}Mo shielding in $(\text{MoO}_n\text{S}_{4-n})^{2-}$ anions.

A typical result with MONALISA was the detection of the ^{34}S - ^{32}S mass-induced isotopic effect on the shielding of ^{95}Mo in the MoS_2 -/4 ion from a high-resolution spectrum of this quadrupole nucleus.¹²

In the late 1970s we changed to heteronuclear magnetic resonance experiments in solids. Shielding constants and indirect and direct spin-spin couplings¹³ for various nuclei have been evaluated. A typical example was the evaluation of the shielding tensor and the eigenvectors of ^{207}Pb in the crystallographically interesting $\text{Pb}(\text{NO}_3)_2$ single crystal by Alfons Nolle.¹⁴ He showed in 1976 that a second-order quadrupole splitting can be reduced by sample spinning,¹⁵ observing the ^{95}Mo NMR signal in solid $\text{Mo}(\text{CO})_6$.

In the 1980s we changed more and more to the fields of in vivo magnetic resonance imaging and localized spectroscopy, since the University of Tübingen obtained a 1.5-T imager in 1985. Sophisticated imaging methods^{16,17} and localization sequences¹⁸ have been implemented and applied in studies with volunteers and patients.¹⁹ Follow-up studies of leukemic and bone-marrow-transplanted patients are examples.²⁰ A further field of interest, experimentally and theoretically, is the problem of coupled spins in localized ^1H or ^{31}P in vivo spectroscopy.²¹ The whole body imager at the Max Grundig Klinik (near Baden-Baden) is supplemented with a ^{13}C channel, so ^{13}C human in vivo investigations can be undertaken. Finally, magnetic resonance imagers can be used with heteronuclei for large sample spectroscopy at low concentrations²² as well as for imaging; the recent ^{129}Xe gas image at atmospheric pressure²³ is one example.

Luz, Zeev: The Early Days of NMR in Israel

Zeev Luz

The Weizmann Institute of Science, Rehovot, Israel

I first joined the Weizmann Institute (WI) in 1957 as a graduate student in the group of Saul Meiboom. I was actually preparing myself to become a science teacher in an agricultural high school (my own alma mater); however, after completing undergraduate studies in chemistry at the Hebrew University (HU) I had a few months left before reporting to work. Aharon Loewenstein (himself an alumnus of the same high school) urged me to start a Ph.D. and continue it concurrently with my teaching job; so I yielded. In those days chemistry students at the HU had very little exposure to modern science; quantum mechanics was not required and mathematics was taught in huge classes together with all life science students at a high school level. On the other hand, the chemistry students had to struggle through two extensive years of qualitative and quantitative inorganic chemistry. When I joined Meiboom's group it was at its prime, producing extremely interesting work in the forefront of NMR research; double quantum transition and radiation damping were observed, radiofrequency phase control was introduced to pulse sequences, strongly coupled spectra were interpreted and fast chemical processes were investigated by spectral lineshape analysis. Even the first application of the density matrix formalism to dynamic NMR was made there at the time. All these activities were directed by Meiboom, who although appearing shy and reserved, was the main driving force behind the operation. He provided encouragement, guidance, and ideas with a natural instinct to identify meaningful problems. My background was simply not sufficient to join in the excitement, but I was learning and watching. My account will therefore be predominantly that of an observer, describing the work of friends and colleagues, mainly during the period 1954–61, which could well be termed 'the early days of NMR in Israel'. The account is based on my own recollections, talks with colleagues, and written memoirs done especially for this article. For completeness it should be mentioned that in the late 1950s, Jan Grunzweig (Genosar) at the Israel Institute of Technology (Technion) in Haifa and his (then) student, David Zamir built an NMR spectrometer based on a Pound marginal oscillator and used it for solid state studies of quadrupole nuclei. I shall, however, limit my account to the high-resolution NMR work at the WI.

Felix Bloch was a member of the Board of Governors of the WI and would come to Rehovot almost every year for the Board meeting. As a scientist governor he was expected to advise the institute on scientific matters and in this capacity he persuaded its chiefs to establish a 'nuclear induction' laboratory (as NMR was referred to in those days in Stanford). At that time (1953) high-resolution NMR was in its very infancy; chemical shift and spin–spin interaction had just been discovered, but their potential impact on chemistry was not yet appreciated. In Bloch's laboratory, J. T. Arnold had recently completed the construction of a 7 kG high-resolution proton NMR spectrometer with probably the best magnetic field homogeneity of the time. Bloch suggested that a capable

scientist be sent to his laboratory and replicate the apparatus. Chaim L. Pekeris, the head of the Department of Applied Mathematics, suggested Saul Meiboom, a co-worker in his department who was involved at the time in analyzing seismic signals from underground detonations as part of a geophysical oil prospecting project. Meiboom was born in Belgium and studied physical engineering in Delft (The Netherlands). He arrived in Jerusalem at the outbreak of World War II and participated in the war effort by designing and building electronic devices for military communication. After the war he joined the Department of Applied Mathematics at the WI, and in addition to the geophysical project he also pursued semiconductor research: together with Benjamin Abeles he studied the band structure of germanium and silicon, based on the Hall effect and magnetoresistance measurements. Part of this work became the thesis for his Ph.D., which he submitted to the HU. It was at this stage that Pekeris urged him to go to Stanford. So during the first half of 1954 Meiboom spent several months in Bloch's laboratory, after which he returned with blueprints of Arnold's spectrometer, as well as yet unpublished high-resolution spectra of ethanol, obtained by W. Anderson, in which higher-order splittings were observed for the first time.

Meiboom's first student in the field of NMR was Shlomo Alexander. In the summer of 1954 Alexander was about to finish his undergraduate studies at the HU and was looking for a place to do a Ph.D. in experimental physics. On the recommendation of his father, Ernst Alexander, the senior experimental physicist in Israel at the time, and William Low, who already ran an electron spin resonance laboratory at the HU, Alexander met with Meiboom to discuss possible topics for a thesis. By then Meiboom had already sent out orders for the necessary components for an NMR spectrometer, so they agreed that the construction of the spectrometer would constitute the first part of Alexander's thesis.

In 1954–55 Israel was still under rationing. Import of components involved a lot of red tape and took ages. The country had very little electronic and technological capabilities and was focused on its main concern: the absorption of huge waves of immigrants, mostly unskilled, who flooded the country and needed jobs. The Stanford spectrometer on the other hand was top technology. The success in replicating it under the prevailing conditions was due foremost to Meiboom's skill and drive, but also to the farsightedness of the WI directors, who provided support and help. Construction of the spectrometer started in November 1954 and within six months the first high-resolution spectra were recorded.

The magnet was ordered from a local factory near Petach Tikva (Magen Chetwood, which specialized in producing safe deposit boxes and had the heavy machines and lifting equipment needed for the job, see Figure 1). Its frame consisted of a -shaped yoke, closed with an I-shaped movable cart, both made of forged iron. The magnet poles, held horizontally inside the yoke, consisted of two sets of nine square Alnico rods, capped with soft iron pole pieces. Special attention was given to polishing these pole pieces in order to obtain maximum homogeneity. They were annealed in a hydrogen atmosphere and Meiboom and Alexander perfected their surfaces to optical flatness (as checked by Newton rings) by rubbing them against each other (Figure 2). In doing so they discovered that it was absolutely necessary to start with three pole pieces and rub them pairwise until

Figure 1 The not yet magnetized iron yoke being loaded at the Magen Chetwood factory for delivery to the Weizmann Institute

two were flat enough. The magnet poles were wound with 14 electric coils and used a three-phase Thyatron rectifier. The magnetizing current lasted a few seconds and resulted in burning out the main fuses of the whole WI. It was, however, sufficient to reach the desired field of 7 kG. Homogeneity was further improved by shim coils and sample spinning, or

Figure 2 Saul Meiboom (left) and Shlomo Alexander (right) rubbing a pair of pole pieces against each other to optical flatness

sample wobbling. The field drifted with time and compensating currents drawn from an automobile battery were required to minimize the effect. Because of the thermal expansion of the iron yoke the magnetic field also had a slow seasonal drift: the proton resonance frequency was 31.65 MHz in midwinter and 31.60 MHz in midsummer. The main modification compared with the original Arnold spectrometer was the introduction of a single coil probehead, instead of the Stanford cross-coil configuration. The rf irradiation was applied with coherent (1 kHz) weak pulses while during the time between pulses the coil served as a receiver. This greatly simplified the construction of the probehead, suspended the need to use 'leakage paddles' and eliminated baseline problems. The electronics were based entirely on vacuum tubes which were assembled on a big chassis with a soldering iron (Figure 3). There were very few 'black boxes' and the experiments could readily be controlled and modified by rewiring the electronic circuits. On the other hand there was an irritating dependence on the spectrometer's unpredictable mood and, of course, many of today's capabilities were not even thought of in those days. Much of the subsequent electronic modifications were made by Moshe Sasson, an electronic technician from the Israeli Air Force who joined the group in 1956. Excellent services were also provided by Bernard Feldman, a European-trained mechanical engineer who was hired by Chaim Weizmann in the early 1930s and produced unique fine mechanical devices until his death in 1991 at the age of 84 years.

When in a good mood, the spectrometer produced beautiful high-resolution, T_2 -limited spectra which, because of the low field, exhibited higher-order splitting of the type Anderson had already seen in ethanol and interpreted by second-order perturbation theory. Soon after the spectrometer became operational, Israel Dostrovsky, the head of the Isotope Research Department, showed up in the lab with a few hydrocarbon samples which he wanted to check by NMR. Some of them were vinyl derivatives which showed complex spectra due to the strong coupling between the three olefinic

Figure 3 Saul Meiboom and the NMR spectrometer. To the right is the magnet with the shimming knobs on the front panel. The four stacks to the left side contain from right to left, a Sanborn strip recorder (which used a hot wire and temperature-sensitive wax paper strips), a CRT screen for displaying the spectra (obtained from military surplus), a Tektronix oscilloscope for controlling the pulse sequences, and a panel for controlling the rf source and the field sweep

protons. Second-order perturbation was not enough to explain the structure and a complete diagonalization of the spin Hamiltonian was necessary. This and the quantum chemical interpretation of the spin–spin couplings became the second part of Alexander's Ph.D. thesis. Fortunately Pekeris and his group had already completed the construction of the WEIZAC computer, the first digital computer in Israel and one of the first in the world outside the USA.¹ It was constructed from vacuum tubes, required $50\ \mu\text{s}$ to perform an addition, had a total memory of 4000 numbers and was programmed in elementary machine language. Help was provided by Philip Rabinowitz, who was the only person in the institute with previous experience in programming. With this monster Alexander numerically diagonalized the 3×3 matrices of the ABC spin systems and interpreted the vinyl spectra. To his surprise he could only fit the spectra if one of the three spin–spin couplings had an opposite sign to the other two.² Opposite signs of couplings involving hydrogen and fluorine were already known from Gutowsky's work, but were not thought possible between hydrogens. This result contradicted the standard molecular orbital picture and demonstrated the importance of the correlation effects between electrons in different orbitals. Intrigued by the result, Alexander constructed an elegant valence bond theory based on the Dirac vector model to provide a satisfactory explanation of the observed couplings.³ Nowadays with 10- to 20-fold higher magnetic fields, such complex spectra are rarely observed and at any rate are considered a nuisance for the experimentalists whose main interests lie in analytical and structural investigations.

Chemical applications of NMR started in Meiboom's laboratory with the arrival of Ernie Grunwald. He was a professor of chemistry at Tallahassee (Florida) and an accomplished physical organic chemist. In the summer of 1955 he came to spend a sabbatical year with Dostrovsky at the WI and soon realized the opportunities offered by NMR. Grunwald was interested in acidity functions of nonaqueous media and expected to be able to measure these from chemical shift changes induced by strong acids. Being physically limited at the time because of a car accident, he needed help with the bench work. So Aharon Loewenstein, who had just finished his M.Sc. at the WI, was invited to join the group as a Ph.D. student and carry out the experiments. His first task was to prepare and measure the proton NMR spectra of dilute ethanol solutions in sulfuric acid–water mixtures, but no S-shaped chemical shift dependence on the sulfuric acid concentration, as predicted by Grunwald, was found. To save the honor of chemistry, Grunwald suggested switching to aqueous media and proposed titrating solutions of methylammonium salts whose $\text{p}K_{\text{a}}$ values were well established. This time the characteristic S-shape function showed up very clearly, but far more interesting were the effects on the spectral structure whereby the spin–spin multiplets would coalesce and resplit as a function of pH. These titration experiments led to the discovery of methods for studying the kinetics of acid- and base-catalyzed proton-transfer reactions in solutions. They resulted in a series of landmark papers^{4–6} in which detailed kinetic analysis of the various protolytic processes in alkylammonium salt solutions were made.

Dynamic effects on NMR multiplets were already known at the time and analyzed by the method of Gutowsky, McCall, and Slichter (GMS), and subsequently by the much simpler

method of McConnell. The spectra were analyzed using so-called 'lineshape parameters' which were dimensionless quantities such as the ratios of peak to trough in exchange broadened multiplets, or linewidth in units of the spin–spin coupling in the fast exchange regime. These parameters were obtained from simulated exchange broadened spectra (using the WEIZAC) but, since no plotters existed, the data were first hand plotted and then used to obtain the theoretical lineshape parameters. For each spin multiplet, exchange mechanism and natural linewidth (field inhomogeneity), a different lineshape parameter versus rate plot was made and subsequently used in the analysis of the experimental spectra. The field inhomogeneity was checked before and after each series of experiments by recording the free induction decay of a reference signal. These decay signals were measured using 'T₂ rulers' which consisted of transparent rectangular plastic pieces on which different exponential decay curves were marked. The rulers were moved over the recorded free induction decay signals until a good fit to a single exponential was obtained.

Another visitor in Meiboom's laboratory in those days was Jerry Kaplan. He graduated from Kittel's group in Berkeley and took a position at the Naval Research Laboratory (NRL) in Washington, DC, immediately after receiving his Ph.D. In 1955 Pekeris passed by the NRL and gave a talk. Someone in the lab knew that Kaplan was interested in visiting Israel and arranged that he would drive Pekeris to the train station. During this trip it was agreed that after appropriate application Kaplan would be awarded a Louis Lipsky Fellowship to the Weizmann Institute. He arrived in the summer of 1956 by boat from Naples, after hitchhiking for several months through Europe. Since there was no physics department at the WI in those days, he was assigned to Meiboom's group.

Chemical exchange studies were well under way in the group when Kaplan arrived. The quantitative analysis of the NMR lineshapes was based on the GMS theory which assumed weak coupling between the nuclei. This was not always an appropriate approximation and so Meiboom suggested that Kaplan extend the theory to the more general case. Kaplan, after a month wandering without getting anywhere, was suddenly struck by the idea of using the density matrix formalism. He combined it with the GMS method into a general theory for calculating dynamically broadened spectra.⁷ He demonstrated the formalism by applying it to the case of a strongly coupled pair of protons, one of which was exchanging with another proton. When Kaplan returned to the USA at the end of 1956 he met H. McConnell who told him about his new way of including exchange phenomena in the Bloch equation. Kaplan incorporated this formalism into a second exchange paper which he wrote shortly after returning to the USA.⁸ An extension of the formalism was subsequently made by Alexander, who when already at Bell Laboratories, was asked by Meiboom about the form that the linewidth equations should take for a spin–spin multiplet in the fast exchange regime. Alexander, who was unaware of Kaplan's second paper, developed the full density matrix analog of the Bloch–McConnell equations for both mono- and bimolecular reactions. Two papers emerged⁹ which are Citation Classics to this day. Ironically it took a few years until they were appreciated by the NMR community: a minor typographic error in the example provided in the paper (the numeral one was substituted for the letter i in two places in the final equations) resulted in incomprehensible lineshapes. C.S.

Johnson and M. Saunders (from Yale) were diligent enough to go through the derivation and detected the error. They made good use of the theory afterwards.

Another problem that Kaplan worked on was the double quantum effect. On reading the Wangness–Bloch paper he realized that a double quantum transition should be observed under strong rf irradiation and he calculated its transition probability. Meiboom then confirmed the theory by experiments on ethanol where a double quantum peak indeed appeared midway between the methyl and methylene signals. They submitted the results for publication¹⁰ in January 1957 and then discovered that two months earlier a note by W. Anderson¹¹ mentioned the observation of the effect in chlorobromothiophene. Kaplan and Meiboom recognized that the ‘interpretation of complex multiplet structure may be facilitated by finding the double quantum transition’,⁷ an idea that many years later was effectively exploited by Alex Pines.

To achieve homogeneity it was customary to spin the samples by air turbines. This worked well with glass tubes. In an attempt to improve the homogeneity even more, sample holders with spherical cavities were also employed. These were constructed of two Rexolite rods, each ending with a hemisphere hole. When put together these hemispheres formed a spherical cavity in which the liquid sample was placed, but the combined Rexolite twin rod would not spin properly. So instead it was wobbled back and forth by a string connected to a car windshield motor. This drove Kaplan to perform a theoretical analysis of the effectiveness of the different motions on line narrowing. He concluded¹² that a periodic rotation was generally more effective, so the Rexolite sample holders and the windshield motor were abandoned.

The next student to join the group was David Gill, a physicist with a chemical engineering background. He started his research work by measuring transverse relaxation in aqueous solutions of paramagnetic ions, but his main project was to explain the T_2 anomaly of water, namely the observation that the proton transverse relaxation rate (but not T_1) is enhanced at around pH 7. The possibility that the effect was due to oxygen-17 was rejected at the time because it was not believed possible that a rare isotope with a natural abundance of 4×10^{-4} could have any effect. Instead, the phenomenon was interpreted in terms of fast exchange between two types of chemically shifted protons: hydrogen bonded and non hydrogen bonded. If the breaking and reforming of hydrogen bonds were catalyzed by H^+ and OH^- ions, a minimum in the exchange rate and a corresponding minimum in T_2 should result at around pH 7 where their concentration is lowest. Unfortunately the only result still valid from the publication¹³ in which the effect was announced is the very useful equation for T_2 in the fast exchange limit. Used in many applications, this equation gives the width of a coalesced line involving exchange between two chemically shifted sites with arbitrary relative populations. After permanently moving to Bell Laboratories in 1958, where he used a 60 MHz spectrometer, Meiboom discovered that the T_2 anomaly (which according to the original model should have increased quadratically with the field) was not due to chemical shift after all. Instead he showed¹⁴ that the anomaly was indeed due to spin–spin coupling with oxygen-17, modulated by acid- and base-catalyzed proton exchange between water molecules. Meiboom even determined the proton–oxygen-17 coupling constant which was subsequently

confirmed (by J. Ruben and D. Samuel at the WI) by direct measurements. Ironically, the WI was the world’s main producer of oxygen-17 (and oxygen-18) enriched water. Gill needed only to borrow a sealed vial of oxygen-17 enriched water and observe an enormous broadening of the proton signal. In fact Dostrovsky, who 10 years earlier built the oxygen isotope separation plant at the WI, realized quite early the potential importance of oxygen-17 NMR. In the late 1950s he assigned Charles Braude to build an NMR spectrometer dedicated to oxygen-17; however, the project never got off the ground. In the early and mid-1960s a first commercial NMR spectrometer (a Varian DP60) was purchased by the WI. Daniel Fiat and his (then) students (including Jacques Ruben, Alexander J. Vega and Abraham Achlama) made extensive use of the availability of oxygen-17 for NMR studies, particularly for hydration problems. Somewhat later Brian Silver and I used it for ESR studies of oxygen-17 labeled radicals in solution and in solids.

Gill had difficulties in measuring long T_2 decays using the Carr–Purcell train scheme. At high pulse repetition rates the results became quite sensitive to the adjustment used: echo decays which ideally should be exponential often exhibited beats and other irregularities, although on rare occasions beautiful exponential decays were also observed. Gill realized that the effect could be due to phase errors accumulated as a result of imperfections in the widths of the 180° pulses. He first thought of correcting the error by inverting the phase of every other π pulse in the sequence. However, Meiboom soon realized that the much simpler experiment of shifting by 90° the phase of only the first 90° pulse in the sequence gives the same result. This modified sequence results in self-correcting phase errors, unlike the original Carr–Purcell scheme which results in an unstable state with accumulating errors. In the modified scheme, beautiful exponential decays were observed that were quite insensitive to the pulse width adjustment. As of now this so-called Carr–Purcell–Meiboom–Gill (CPMG) sequence is still the preferred method for measuring T_2 in liquids. The paper describing the experiment¹⁵ is recognized as the first in which the importance of maintaining specific phase relations in pulse experiments was emphasized. It had a tremendous effect on the development of pulse techniques and is today one of the most quoted in the NMR literature.

Another experiment related to the ‘rotating frame’ picture which was conceived at the WI but actually implemented at Bell Laboratories, became the forerunner of many ‘solvent suppression’ methods. Meiboom, in one of his rare letters to the group in Rehovot, mentioned that in order to measure the transverse relaxation rate of the methyl and hydroxyl signals in methanol separately, he was using ‘weak pulses’. When Alexander met Meiboom at Bell Laboratories, he complimented him on the ‘clever idea’ of tilting one magnetization without affecting the other. After a short discussion they realized that they understood the term ‘weak pulses’ quite differently. While Meiboom simply implied that $\gamma B_1 < |\Delta\nu|$, Alexander thought of an experiment in which a 90° pulse was applied to one signal at resonance, $\gamma B_1 \tau_p = \frac{1}{4}$, while the other signal, $\Delta\nu$ Hz away, made a full rotation about its own effective field, $\tau_p[(\gamma B_1)^2 + (\Delta\nu)^2]^{1/2} = 1$. They immediately tried the experiment, obtaining beautiful CPMG decay echoes for one peak of methanol without the interference effect of the other.¹⁶

In 1957 three new students joined the group: Abraham Szöke, a physicist, and Mati Sheinblatt and myself, both chemists. We three closed the list of Meiboom's students at the WI since a year later he left permanently for Bell Laboratories. Szöke worked on two practical problems related to high-resolution NMR. His main project was to confirm and determine quantitatively earlier theoretical predictions on the coupling between the precessing magnetization and the receiver coil. The coupling was regulated by an amplifier which was fed with measured doses of both positive and negative feedbacks (Q -multiplier). At high Q very dramatic radiation damping of the FID signal was observed following a 90° pulse, while a 180° pulse yielded beats due to two level maser emission.¹⁷ The effect was sufficiently impressive for A. Abragam (who visited the WI at the time that these experiments were performed) to reproduce a picture from Szöke's work in his 1961 book entitled 'The Principles of Nuclear Magnetism'. Szöke also designed and successfully operated field-locking NMR oscillators. Many designs worked but the winners in commercializing the device were others.

Sheinblatt and I were fascinated by the ability of NMR to measure fast chemical processes. Here one could calmly sit next to a spectrometer and measure processes, at equilibrium, having mean lifetimes as short as milli- and even microseconds. Sheinblatt extended Loewenstein's work to amino acids and later to peptides and oligopeptides, with the purpose of developing methods for sequencing. In that he certainly was one of the pioneers in applying NMR to biological research. I chose to work on proton exchange in hydroxylic solvents but after Meiboom's departure I joined forces with Brian Silver to work on the NMR of phosphorus compounds.

After Meiboom's departure for Bell Laboratories, Low would arrive weekly from Jerusalem to supervise Meiboom's orphans. However the day-to-day guidance was provided by Alexander, although he had just finished his Ph.D. At that time Szöke experimented with double irradiation and Gill attempted to build an NMR magnetometer for the detection of ground anomalies that could be used for example in archeological survey. Sasson and Bruno Bienenfeld (who later moved to Hewlett Packard in Palo Alto) provided excellent electronic services for these projects.

At the end of 1961 I finished my Ph.D. and joined Meiboom at Bell Laboratories as a postdoctoral fellow. At the same time I also discontinued my occupation as a high school teacher. Among the pupils in the last class that I taught was a 16 year old youngster by the name of Alex Pines. He will often be mentioned in this Encyclopedia. Meiboom had just explained the oxygen-17 induced T_2 anomaly of water, and together we extended the study to aqueous solutions of buffers in order to determine the average number of water molecules participating in single proton-transfer steps (the so-called Grothaus mechanism). In one of these studies we used an idea of Meiboom's to measure the CPMG echo decay as a function of the pulse repetition rates.¹⁸ The experiment allowed the determination of exchange rates in the fast limit even when the interaction parameters were not known: they were obtained together with the kinetic parameters from the dependence on the pulse repetition rate. The method was rediscovered several times and, although not very widely used, it found some useful applications in polymer and membrane research. It would have probably become more popular had Meiboom invented an acronym for it!

To get away from proton-transfer processes, I started to study relaxation effects in solutions of paramagnetic ions. Just when I was beginning to understand what was happening, the famous paper by Swift and Connick appeared (I remember Bob Shulman, who showed interest in my work, entering my room with the latest issue of the *Journal of Chemical Physics*, asking 'Have you seen this?'). It provided a complete explanation of the oxygen-17 T_1 and T_2 relaxation in aqueous solutions of paramagnetic ions in terms of the exchange parameters between the bulk and the hydration shell molecules and the magnetic parameters of the ions. The signal of the hydration shell was, however, not observed at the time because of its excessive width caused by the electron-nuclear hyperfine and dipolar interactions and by the chemical exchange. On reading the article I was of course quite frustrated, but recovered after a few days when I realized that by switching to methanol as a solvent I should be able to extend the study and see even more. Since methanol solutions can be cooled down to almost -100°C , the exchange of solvation shell molecules could be frozen out, allowing their direct observation by NMR. This turned out to be very fruitful: solvation numbers could be determined, the magnetic properties of the solvation molecules could be directly studied, and the effects of mixed ligands on the solvation shell structure were clearly seen.¹⁹ The period (1963) was the beginning of the biological application of NMR. 'Solvent relaxation enhancement' by paramagnetic active sites in enzymes was a favorite subject and these direct quantitative studies of the solvation shells provided much insight for the biological work.

Eight years later I spent another year with Saul Meiboom at Bell Laboratories, collaborating on NMR in liquid crystals, a field of research that he pursued at the time with L. Snyder. He continued to study liquid crystals using a variety of other experimental methods and eventually shifted to theoretical calculations on the structures of the cholesteric blue phases, until his retirement in 1986. Shlomo Alexander who spent a postdoctoral period with P. W. Anderson at Bell Laboratories returned to the WI where for several years he ran an experimental laboratory in pure quadrupole resonance spectroscopy. In 1968 he moved to the HU to become a theorist in condensed matter physics. Twenty years later he returned to the WI. Ernie Grunwald followed Meiboom to Bell Laboratories and after several years moved to Brandeis University where he continued his studies in physical organic chemistry until his retirement in 1990. Aharon Loewenstein went as a postdoctoral student to J. D. Roberts at Caltech and then to B. Dailey at Columbia University. He later accepted a position at the Technion in Haifa working mainly on quadrupole nuclei and liquid crystals. Jerry Kaplan left Rehovot in the fall of 1956 and traveled through Asia to California. He then worked for many years at Battelle Institute and later settled in Indiana University. Mati Sheinblatt spent a postdoctoral training period with H. S. Gutowsky in Urbana and later with E. D. Becker at the NIH. Shortly after returning to Israel he accepted a position in the newly established Tel Aviv University and continued to work on the NMR of peptides. He passed away in 1989. Moshe Sasson became the first professional Bruker representative in Israel, but he too died very young in 1988. Abraham Szöke went for postdoctoral training to MIT where under A. Javan he switched to laser physics. He then joined Tel Aviv University but later moved to Livermore, California until his retirement in 1993.

David Gill, after a postdoctoral period with N. Bloembergen at Harvard, joined the HU and then spent several long periods in the United States. He became a biophysicist and in 1974 joined Ben Gurion University in Beer Sheva. Sonja Stollman, the able bilingual Hebrew–English secretary who cheerfully did all of Meiboom’s paper work and typed the Ph.D. theses, left for the United States in 1959 and has since been living in New York City.

In 1964 I returned from my postdoctoral training to the WI where I have continuously held the torch of magnetic resonance. Many excellent NMR spectroscopists spent extended periods at the WI throughout the years including Daniel Fiat, Jacques Reuben, Mordechai Shporer, Abraham Achlama, Eva Meirovitch, and others. In the early 1990s NMR research has been pursued in essentially all universities and scientific institutions in Israel. The largest group is still at the WI where the activities range from solid state and theoretical NMR to biological application and imaging, with an enthusiastic group of scientists which includes Jacob Anglister, Peter Bendel, Hadassa Degani, Daniella Goldfarb, Irina Kustanovich, Aviva Lapidot, Michal Neeman, Raphi Poupko, Shimon Vega, and many young students.

Lynden-Bell, Ruth M.: Reminiscences of Early Days of NMR

Ruth M. Lynden-Bell

The Queen's University, Belfast, UK

When I started my Ph.D. at the Chemical Laboratory in the University of Cambridge in 1959, nuclear magnetic resonance was a new spectroscopic technique. I joined Norman Sheppard's research group at the same time as Robin Harris; the other students working on NMR were Jim Turner and Colin Banwell.

The spectrometer that we used was a large 40 MHz Varian instrument that lived in the basement. It had an electromagnet which was over 1 m in diameter whose power supply occupied a large rack of electronic equipment and included the biggest valves I had ever seen. One realizes the enormous changes that computers have made to spectroscopy when one looks back at the way the instrument operated. In 1959 there were no computers attached to spectrometers, FT spectra were unknown in NMR and everything was one-dimensional. Each spectrum was a single scan of the magnetic field which came out on a narrow strip of heat-sensitive paper, and was burnt on the paper with a hot pointer. We were interested in measuring chemical shifts and spin–spin coupling constants of small molecules accurately and for this one selected each line or a few lines in turn, added frequency markers by generating sidebands of the standard (usually TMS) and then scanning slowly back and forth many times. One then measured the peak positions with a ruler.

To get the best—that is the most uniform—field from the spectrometer was a skilled operation. The technician in charge of the instrument, Eric Liddell, was adept at this. The power was shut off over the weekend and every Monday morning he powered up the electromagnet and then cycled it through a series of hysteresis loops. At first the field would be dome-shaped, bigger in the center of the magnet than at the sides, and after each cycle it would be more uniform and the lineshapes sharper and more symmetric. However one needed to know when to stop. If the cycling process was continued once too often the field would become dish-shaped, with a minimum at the center, giving broad asymmetric lines. This problem was greatly helped when, a few years later, Golay coils were added. These were used to generate small correcting fields to give sharp lines.

The spectrometer had been purchased for organic and inorganic chemists and Norman Sheppard employed to run a service. Most of the spectrometer time was spent on this service. Eric Liddell ran the spectra, which then went to Norman Sheppard for interpretation as in those days most chemists were quite unfamiliar with NMR spectra. By far the largest number of spectra run were proton spectra, but we did have ^{19}F and ^{31}P probes and a low-temperature probe. Those of us in the research group ran our own spectra.

Our research group was friendly and we learnt much from each other. We were in a special position as spectroscopists in a department of organic, inorganic, and theoretical chemistry;

at that time the physical chemists were a separate department. Pople, Schneider, and Bernstein had published their comprehensive book on NMR¹ earlier in 1959 and that was where we learnt about the principles of the subject. Years later John Pople told me that they had included every reference up to the date of submission of the manuscript, which shows how young the technique was in 1959. The book is excellent and still provides most of the theory needed by NMR spectroscopists.

The main research interests of the group at that time were to measure accurate values of spectral parameters so that theories could be developed, and to use NMR spectroscopy to investigate conformational equilibria. My original problem was to measure the spin–spin coupling in tritiated hydrogen, HT. The tritium nucleus has spin- $\frac{1}{2}$ and quite a high magnetogyric ratio, so that one should have been able to measure the splitting in the proton spectrum accurately. This project came to nothing as my attempts to dissolve H_2 in a solvent under pressure to get a signal failed. I was more successful in the next stage of the project which was to use ^{13}C substitution to obtain all the coupling constants in acetylene, ethylene, and ethane. The source of ^{13}C was substituted BaCO_3 and I practised the syntheses many times before opening the bottle of precious labeled material. Luckily the syntheses all went well and I had my samples and could measure the ^1H spectra.² We had no ^{13}C probe, but the following year I visited Varian in California where Jim Shoolery ran the ^{13}C spectra of my samples. In fact the only additional information about coupling constants that one could obtain from the ^{13}C spectra was the relative sign of the HH and CC coupling in ethylene.

In order to analyze our spectra, which were rarely first order, we set up the secular equations using symmetry where relevant. It was all a most pleasing application of quantum mechanics and when the predicted and measured spectra agreed one felt really satisfied. We often needed to diagonalize matrices which were bigger than 2×2 and for that we used a computer. In 1959 computers were very different from those we use in 1993. Most universities had no computer, but at Cambridge we had EDSAC2, which was available to any research student or member of staff. One wrote programs in machine code and the total power was probably about the same as a modern calculator. It was very much a hands-on machine. Once one had written one's program and typed it onto punched tape, one joined the test queue. This was a queue of people waiting at the console and it ran for 15 min three times a day. When one reached the front of the queue one put in one's tape and switched a switch. Ideally the tape should have run through and the results come out on another tape. Programming was just the same then as now—programs didn't work first time. One frequent error was for the machine to get into an endless loop. There was a loudspeaker attached to the computer and when this happened it changed its tune. One switched off the computer, removed one's tape, rushed round to the back, edited the tape, and rejoined the test queue. Once one's program was working one submitted it to the job queue. The job queue was a pegboard with hooks on which one hung one's reel of paper tape for the operators to run at times when the test queue was not running. Library subroutines were available—we used a matrix diagonalization subroutine. These were on rolls of colored paper tapes, and one added a copy of the relevant one to one's own white reel.

NMR was fun in those days, and although I have since completely changed the field of my research, I am sure that NMR is still fun today.

Maciel, Gary E.: A Little Polarization Can be Good for You

Gary E. Maciel

Colorado State University, Fort Collins, CO, USA

THE MIT YEARS, 1960–61

My first awareness of NMR, as I recall, came about when I was an organic chemistry graduate student at MIT about 1958–59. I took a course in statistical thermodynamics presented by a very impressive young assistant professor, named John Waugh, who was engaged, according to graduate student scuttlebutt, in an elegant new (to chemists) phenomenon called nuclear magnetic resonance. During that period, my research supervisor was Frederick D. Greene III, a physical organic chemist, who called my attention to an exciting new book by John D. Roberts on NMR for organic chemists. Many organic chemists seemed to accept the proposition that, if Jack Roberts was interested in NMR, it was probably going to be important in organic chemistry. The eventual decisive manifestation of that proposition is perhaps a good calibration on Jack Roberts's insights and on the wisdom of organic chemists in paying attention to his interests. Jack Roberts's little book was aesthetically appealing, filled with beautiful vector diagrams (including red coloration, which was unusual in technical books at that time), and was quite seductive to an impressionable young chemist.

One of the hot areas in NMR research at the time was the analysis of second-order spectra, e.g., AB, ABC, etc., spin systems and the Roberts book gave a hint of the joy involved in the back-of-the-envelope (sometimes a large envelope) quantum mechanical calculations involved in these spectral analyses. I was delighted to learn that John Waugh was involved in this kind of research, so I decided that it would be fun and educational for a physical organic chemist to spend a year in John Waugh's lab, learning about NMR—and, hence, getting some experience in quantum mechanics. To the extent permitted by the time constraints while finishing my Ph.D. thesis (concerned with the bromination of bibenzyl with *N*-bromosuccinimide—no NMR there!), I became an occasional 'NMR groupie' in the Waugh lab, and was suitably impressed by students and visitors of the quality of Richard Fessenden (now at Notre Dame) and Robert Blinc (whose affiliation then, as now, was Ljubljana in what was then Yugoslavia). I remember one occasion, when John Waugh was trying to convince the Dean that the NMR lab was overcrowded and needed additional space (John had previously escaped from his initial cave under a stairwell). John asked me, along with a few other 'ringers' to pack his lab during the Dean's visit. The effort was a success.

The National Science Foundation accommodated my desire to spend a postdoctoral period in John Waugh's lab by awarding me a much-appreciated fellowship. My time in John Waugh's group (1960–61) was enormously educational

for me, if not spectacularly productive for John (he *insisted* that students and postdocs call him by his first name; this was my first experience with this kind of informality among university faculty). I quickly learned that one should not be too intimidated by commercially provided instrumentation (e.g., NMR probes); if something built by *man* (even specialists at Varian, which was in many respects the center of the NMR universe at that time) was taken apart or even broken by man, it could always be repaired or rebuilt by another mortal man (there were no women in the Waugh group at that time, and very few in the entire MIT Chemistry Department).

During the period 1960–61, state-of-the-art in NMR spectrometers was a Varian HR-60, a field sweep high-resolution CW instrument. Just before I joined the Waugh group, one of the major technical problems in the lab originated in the water cooling system for the electromagnet; the NMR lab was directly below a men's restroom, and sometimes during a change of classes, enough toilets would be flushed at the same time to reduce the water pressure sufficiently to cause the pressure sensor of the magnet circulation system to shut down the magnet. Very annoying! This problem was, of course, solved by the introduction of a closed-circuit water cooling system.

John Waugh's laboratory at MIT was an enormously stimulating environment for a young scientist (even a physical organic chemist) to begin learning about NMR, not only because of John himself, but also because of some excellent students. I worked closely with Charles Johnson (now at the University of North Carolina), who impressed me greatly without trying, and from whom I learned a great deal. Fred Mannis, who went to DuPont upon completion of his Ph.D. thesis, was also very helpful and knowledgeable. In those days, smoking was much more common, even in the laboratory, and I have visions of Joe Gavin (a joint Waugh–Stockmayer student who later took jobs at the CIA and Perkin-Elmer, presumably not simultaneously) leaning over the Harvey-Wells magnet while he set up and observed his self-diffusion measurements (based on field gradients generated by the current from a bank of car batteries), cigarette dangling from his mouth, and smoke effectively screening the desired observations from his view. This smoke obviously caused his eyes great distress; but, he maintained, it was worth it! During this period I became acquainted with Gary Mennitt, who joined the faculty of the City University of New York after leaving the Waugh laboratory. Many years later (1980–81) Gary spent a sabbatical year with us in Colorado, during which we had some fun exploring ^{113}Cd chemical shifts in the solid state.

My 18 months in John Waugh's laboratory were a real learning experience for me, and mercifully NSF picked up the tab for my support. I dabbled in a few areas, which included obtaining and analyzing some relatively complicated high-resolution ^{19}F NMR spectra, an area in which we collaborated with Dietmar Seyferth. During that same period we collaborated with Gordon Hammes, then on the MIT faculty, on the first (I think) study of what subsequently became a very popular subject, the NMR investigation of interactions between metal ions and ATP.

Probably my favorite 'miniproject' at MIT, the one which allowed (forced) me to delve into the instrumental side of NMR (e.g., those marvelous tube-based, analog Tektronix waveform/pulse generators), was based on John Waugh's recognition that the Fourier transform of the transient

signal from a J multiplet, following a pulse, would contain high-resolution information regarding the multiplet structure. Furthermore, he recognized that if this experiment were carried out in a spin echo mode, one could avoid most of the problems associated with magnetic field inhomogeneity (a substantial issue in 1960). I left MIT before this project bore fruit, but I personally benefited greatly from the experience.

One terrific piece of luck in the timing of my postdoctoral period in John Waugh's group was the fact that Charles Slichter of the University of Illinois was spending a leave at the 'little red schoolhouse' down the street from MIT (this is how we affectionately referred to Harvard University), and was presenting a special course on nuclear magnetic resonance. This was a beautiful set of lectures and resulted, I believe, in the terrific book from which so many of us have profited since that time.

While it was Roberts' early books that attracted my attention to NMR initially, it was the magnificent book by Pople, Schneider, and Bernstein that I, and many others, really used to begin *learning* NMR. Initially it seemed like *everything* was in there, but I finally began to realize that there was much more to learn when John secured a copy (in 'blue ditto' form, as I recall) of the manuscript for the NMR bible by Abragam. That manuscript, which was in French, was circulated covetously through the group in a manner that reminded me of French postcards in high school.

THE UNIVERSITY OF CALIFORNIA, DAVIS YEARS, 1961–70

It seems almost impossible for me to believe now that I spent nearly 10 years in Davis, a period during more than half of which my wife, Maxine, had to put up with the difficulties of living with the typical insecurities of an untenured faculty member. I went to Davis in 1961, somewhat of an impostor as a physical chemist, with the intention of developing ^{13}C NMR as an approach for studying the structures of organic compounds, e.g., carbon connectivities, in liquid samples (we hadn't yet started dreaming about solid samples). Paul Lauterbur (then at the Mellon Institute) and C. H. Holm (Shell Development) had just produced two or three publications that clearly indicated to any organic structure oriented NMR researcher the enormous potential of ^{13}C NMR, even if one considered the daunting difficulties of obtaining ^{13}C spectra at that time. An impressive new Varian HR-60 spectrometer was awaiting me when I arrived in Davis, and the Department of Chemistry had equipped it at my request with a probe and rf unit (my assistant professor start-up package!) that was capable (in favorable cases) of detecting ^{13}C resonances. This equipment, which substantially predated field/frequency lock capabilities, was quite suitable for rapid passage/field sweep techniques (in which the peak maximum for one sweep direction was not at exactly the same place as the peak minimum for the other sweep direction—but an average value gave a good measure of the chemical shift). It was this crude approach that we, as well as Dave Grant's group at the University of Utah and Jake Stothers at the University of Western Ontario, used to explore the relationships between ^{13}C chemical shifts and molecular structure.

During this period I was very fortunate to be joined in this ^{13}C NMR effort at Davis by George Savitsky, who had

started as an assistant professor in the department at the same time I started, although he was about 10 years older than me. George, who was a superb researcher and a brilliant teacher, had come to Davis by way of Princeton (postdoctoral research in infrared spectroscopy with Donald Hornig), the University of Florida (Ph.D. studies in physical chemistry), the Dominican Republic and Honduras (soil scientist with the United Fruit Company), the Philippines (a displaced persons' camp), and China (born, raised, educated in the expatriate Russian community, and then forced to leave at the time of the Communist revolution in 1949). George Savitsky was trained as an infrared spectroscopist; but when he arrived in Davis and learned that there was no research-grade IR equipment, he decided to take advantage of the only state-of-the-art spectroscopic equipment in the building—the HR-60 spectrometer. Hence, George and I pooled our ideas and resources and collaborated closely (although we were advised that, for tenure reasons, we should also develop some independent ideas and publications). George was enormously innovative, and was one of the key figures in establishing and correlating the constitutive and additivity properties of ^{13}C chemical shifts. After about five years at Davis he moved to Clemson University (from which he recently retired) where he again used the equipment available to him (no ^{13}C NMR facility)—initiating a successful research program on the study and use of deuterium quadrupolar interactions for the determination of molecular correlation functions.

George had two graduate students working under his supervision at Davis, and hence closely with our group. Keishi Namikawa earned an M.S. degree and went back to Japan, after making a substantial contribution to the study of constitutive effects on ^{13}C chemical shifts. Bob Pearson was much more independent in his research than most of our students; he went on to Kaiser Chemical Corp., where he became a pioneer in the use of NMR for on-line process control, a subject that he now pursues as a principal in Tri-Valley Research, Inc.

During the period while George Savitsky and I were working close together and sharing the HR-60 spectrometer, the Davis campus was undergoing a major transformation, from primarily an agricultural campus to a general campus. As part of that transition, the old Crocker cyclotron was (at least nominally) being moved to Davis, rebuilt and installed in a magnificent new building. Part of the apparatus being moved to Davis was an old NMR console/probe system, used for calibrating magnetic fields, and the physicists at Davis brought it over to our laboratory to calibrate it with the HR-60 magnet. While this calibration was being carried out, I noticed that the manufacturer's label was 'Varian Associates' and the apparatus was marked 'Serial No. 1'.

During my first few years in Davis in the early 1960s, Stan Burdick,* of whom I have lost track (Stan, please call if you see this!), Charles Carmen (who went on to an outstanding research career at B. F. Goodrich), and John Natterstad (who is now in the instrumentation industry in the northwest) were M.S. students in the group and got things started. John carried out some of our first ^{13}C experiments on the effects of substituents, hydrogen bonding, and protonation on carbonyl groups. Soon after George Savitsky left Davis (in about 1965), we moved into a spacious new building, which came equipped with a Varian HA-100 spectrometer (now, at last, a field/frequency lock system!). About the time we acquired the HA-100, Don Hofer and George Gray joined the group,

Don working on ^{19}F chemical shifts in fluoride solutions and George measuring ^{13}C – ^{13}C J couplings in dilabeled compounds that *he synthesized*. After a time at the University of Illinois and the University of Arizona, Don moved to IBM, where he works at the Almaden laboratory. George Gray spent a few years as one of the first faculty members of the newly established Oregon Graduate Center (now the Oregon Graduate Institute of Science and Technology), before joining Varian, where he is an applications scientist.

One thing that livened up our Davis laboratory, and enhanced our productivity, was the fact that we had several long-term visits by Dan Traficante, who now has ‘his own series’ and is on the faculty of the University of Rhode Island, but was then an Air Force lieutenant at the Frank Seiler Laboratory of the Air Force Academy, and had earlier been an organic chemistry lab-mate at MIT. Dan had, I suppose, convinced the Air Force that ^{13}C NMR was essential to the security of the free world, so they allowed him to visit us for weeks or months at a time, during which he would feverishly synthesize needed compounds (especially ^{13}C -labeled ones) and obtain their ^{13}C NMR spectra. As had happened to me a few years earlier, Dan was irreversibly infected at Davis by the NMR virus (from which there is seldom a full recovery before death).

Our venture into truly *high-resolution* ^{13}C NMR, with spectra that looked almost as good as those organic chemists obtain routinely today (in much, much less time), depended on computer time averaging (based on a CAT, for computer of average transients), which was made possible originally by our development of a field/frequency lock technique for the HA-100 based on the signal of ^{13}C -enriched carbon disulfide, and ultimately was made much easier by the efforts of Tom Nakashima (who has been on the staff of the University of Alberta for many years) and Vic Bartuska (who recently retired from Chemagnetics), who developed a ^{19}F field/frequency lock system for the HA-100 spectrometer. Although their Ph.D. thesis projects were much more chemically oriented, they both found that they enjoyed working with electronic instrumentation. Vic had been an organic chemist focusing on carbohydrates before joining our group. (He occasionally reminds me that he joined our group only because the carbohydrate chemist in the department stopped accepting students.) He found that instrumentation was more fun than chemistry and subsequently made his career in the NMR instrumentation industry. I’ll never forget how Vic ‘trained’ the field/frequency lock system, based on audio modulation at 2–3 kHz, to respond to his whistling. He could walk into the spectrometer room and cause the spectrometer to lose lock, and then relock by whistling appropriately.

During the Davis period, we were very much influenced in our ^{13}C work in the early to mid-1960s not only by Lauterbur’s seminal papers, but also by extremely important papers by Spiess and Schneider on substituent effects on ^{13}C chemical shifts, and by the theoretical (molecular orbital) treatments of ^{13}C chemical shifts by John Pople and Martin Karplus, and their co-workers. During the 1967–68 academic year, I was able to indulge my interest in ^{13}C chemical shift theory with a sabbatical leave split between Karplus’s group at Harvard University, where I mainly studied formalism, and Pople’s group at Carnegie-Mellon University, where I got serious about computational theory, mainly INDO calculations of J couplings, and developed a collaborative arrangement

with postdoc James McIver, who subsequently joined the faculty at SUNY, Buffalo. I took the enthusiasm and essential computer routines for perturbed molecular orbital calculations of second-order properties (e.g. J coupling and chemical shifts) back to Davis and thoroughly infected my students with this enthusiasm, especially Paul Ellis (who recently moved from the faculty of the University of South Carolina to the Pacific Northwest Laboratory, PNL, in Richland, WA). Jim McIver collaborated with Paul and myself on ^{13}C chemical shift theory at the INDO level, which we found to be surprisingly successful (although not as accurate as later *ab initio* calculations). In Paul’s natural mode of operation, he was soon running the campus computer and also had a substantial amount of time on one of the computers at the Lawrence Livermore Laboratory.

In addition to Paul Ellis, we were fortunate in the late 1960s in having a series of very good students, some of whom moved with me in 1971 to Colorado State University. These included: Harry Dorn, now a professor at Virginia Polytechnic Institute; Tom Nakashima; Larry Simeral, who went on to Ethyl Corporation, now Albemarle Co.; Mark Bacon, who spent a few years on the faculty at the University of Nevada in Reno and at Decatur University in Illinois, before settling into the electronics industry; and Kim Summerhays, who has been on the faculty of the University of San Francisco for several years.

During the Davis years, our group had its first ‘real postdoc’, Dieter Lauer, from Germany, who joined us in our detailed study of substituent effects (including deuterium isotope effects) on ^{13}C chemical shifts. Jointly with Ken Musker, an inorganic chemistry faculty member in the department, I also advised a student, Roger Scholl, who went to work for the Sierra Club after completing his Ph.D. studies. Roger carried out one of the first detailed experimental studies of structure–shift relationships in ^{29}Si NMR spectra of organosilanes. An old friend (he’s *much older* now) and undergraduate classmate in the 1950s in Berkeley, Professor Edwin Motell of San Francisco State University, worked with us periodically at Davis on a variety of ^{13}C chemical shift studies, and continued to collaborate with us after we moved to Colorado State University (CSU) in 1971.

THE CSU YEARS, 1971–PRESENT

Spurred on by the inspiring academic initiatives of Ronald Reagan, who was Governor of California at the time, we moved from the University of California, Davis to CSU in 1971. One of the things that made the decision to move to Colorado a little less impulsive and less crazy than it may have appeared was the fact that CSU had waiting for me a new Bruker HFX-90 spectrometer, bought originally for Alan Jones, who had left CSU before having a chance really to use the new spectrometer (he was a British citizen, who was not able to solve his visa problem, so he moved to Alberta and eventually to Australia). The HFX-90 was a state-of-the-art CW spectrometer and there were funds available for an FT data system to add to the spectrometer.

When we arrived in Fort Collins, the HFX-90 stood silent in a dark, dusty room in a musty basement of the old chemistry building, covered by a plastic tarp. Tom Nakashima and Harry Dorn soon had it purring, and a new age of spectrometer

capabilities was upon us. A few months later, we moved the HFX-90, complete with its 9000 lb magnet, to a new chemistry building across campus. I was enormously impressed when the students were obtaining spectra of reasonably good quality just two hours after the movers set the magnet in place in the new laboratory.

At this time, the only commercially available FT NMR spectrometer was a Bruker HFX (or HX) system with a DEC PDP-8 minicomputer for Fourier transformation and a Fabritek (later Nicolet) signal averager. Digilab offered the only other stand-alone FT NMR accessory, based on a Data General minicomputer with a disk for storage, and we soon had a Digilab system installed on the Bruker spectrometer. This was, I believe, one of the first five or six FT NMR spectrometers in the world. It allowed us to not only continue our work in ^{13}C NMR, but also to branch out conveniently to a variety of other nuclides. The students were aided enormously by the appearance at about this time of the beautiful and timely little book by Farrar and Becker on pulse and Fourier transform NMR.

In addition to the Davis graduate students mentioned above (Harry Dorn, Tom Nakashima, Larry Simeral, Mark Bacon, and Kim Summerhays), there were two students I had met in California when they were undergraduates who moved to CSU to join our group—Jerry Dallas, who subsequently spent several years at GE NMR and is now doing protein NMR at Berlex Biosciences, and Rich Elliott, who left CSU after a couple of years for Wisconsin, where he went to medical school, eventually becoming a psychiatrist. Using the FT version of the HFX-90 spectrometer, Jerry Dallas carried out extensive work on ^{207}Pb NMR, and Marie Borzo (now at Hoechst-Celanese) explored ^{113}Cd and ^{199}Hg chemical shifts, as well as some theoretical aspects of nuclear Overhauser effects. Larry Simeral worked on ^{25}Mg and ^{67}Zn NMR in aqueous solutions, and Joe Ackerman (now a professor at Washington University) studied ^{109}Ag , ^{67}Zn , and ^{113}Cd chemical shifts from the point of view of solution structure. Tom Orr (now at Procter and Gamble) participated in ^{113}Cd studies of Cd(II) complexation, along with leading our subsequently aborted effort in ion cyclotron resonance. Most of the students during this period, especially Harry Dorn and Tom Nakashima, also participated actively in ^{13}C NMR, and some of them continued our computational-theoretical work on ^{13}C chemical shifts and J coupling, along with Don Miller (a postdoc, since then on the chemistry faculty of Washburn University). On the theoretical side, Kim Summerhays emphasized a molecular orbital trick that we called the ‘pseudo atom effect’ for examining substituent effects from a point of view based more-or-less on popular concepts in physical organic chemistry, and Kurt Seidman (now a professor at Randolph Macon Women’s College) examined conformation and medium effects on ^{13}C chemical shifts; later Mary Severson (now a patent attorney in Atlanta, after a few years as a faculty member at Mercer University) continued theoretical studies of certain structural effects on ^{13}C chemical shifts and J couplings. During the past few years, our efforts in chemical shift theory have been extended to ab initio methods, mainly by Joe Iwamiya (now at Lockheed) and Dong-Hee Kim (a sabbatical visitor from Kunsan National University, Korea). During the 1970s, only Michael Heller (a joint student with Anthony Tu in our Biochemistry Department) broke our pattern of largely missing

out on the revolution in NMR applications to the determination of protein and polynucleotide structures.

During the late 1970s and early 1980s, we continued working on a variety of high-resolution multinuclear MR projects on liquid samples, and also continued to dabble in little instrumentation developments and tricks, mainly in electronics. The liquid-sample studies included some ^7Li , ^{23}Na , and ^{27}Al studies of ionic interactions by Wrocklaw Kolodziecki (a postdoc, now with J. Klinowski in Cambridge) and Joel Gray (who recently left Coors after many years in the analytical laboratory), and our first attempt at NMR-based quality control, the determination of sucrose in sugar beet juice, in the work of Doug Lowman (who has been at Tennessee Eastman for many years). During this same period there were major developments that dramatically reoriented our research emphasis toward solid samples, and impacted my career in very important ways. The cross polarization (CP) paper by Pines, Gibby, and Waugh had a profound influence on the way I thought about NMR, and, like many other NMR spectroscopists, I began considering the possibilities of working with solid samples. Also during the 1970s, Schaefer and Stejskal at Monsanto were reviving interest in magic angle spinning (MAS), and married CP with MAS. The prospect of obtaining high-resolution ^{13}C NMR spectra of solids almost routinely was terribly exciting. Having recently moved to Colorado, which was ostensibly on the verge of a major industrial impact based on oil shale, I thought it would be nice, for a change, to do some research that I could explain, or justify, even to my neighbors. ^{13}C CP (and eventually CP MAS) studies of oil shale seemed like the appropriate opportunity to become ‘useful’ to Colorado.

Three other developments came in confluence with my desire to reorient our research group toward solid state NMR studies. One was the emergence at NIH and subsequently at NSF of the concept of NMR Centers. I had already, unsuccessfully, tried to obtain funds from NIH to establish an NMR Center at CSU as part of a Colorado Regional Cancer Center; I was also planning to apply to NSF to establish a center when they eventually announced a broad-based program. During the mid-1970s the establishment of some kind of center seemed to me to be the only possible way of *ever* bringing a ‘high-field’ spectrometer (i.e., one based on a superconducting magnet) to CSU, and to establish an NMR Center with a major solid sample component seemed increasingly attractive to me.

The second development referred to above was that Vic Bartuska, who had spent time at Bruker in Karlsruhe and then at JEOL in Cranford, NJ, after leaving Davis, was unhappy professionally and looking for new horizons. He and I agreed that he should perhaps move to Fort Collins and play a major role in initiating the program I was planning in solid state NMR. This plan would certainly involve extensive instrumentation development, which he found appealing. Although funding was in short supply and very uncertain, we believed that something long term would work out for him so that he and Bettie could raise their family in Fort Collins. The long-term professional possibility that appealed most to Vic was managing the NMR Center we hoped to establish at CSU. As a fall-back position, in case nothing attractive appeared, we agreed that we could establish a small NMR-oriented company of some sort (e.g. NMR accessories) to provide a modest salary and professional challenge for him.

Accordingly, he moved his family to Fort Collins and in 1975 started working on modifying an old HR-60 spectrometer for solid state NMR experiments. His early MAS efforts, which included marginally successful experiments with the 'barrel' design being used at that time by Schaefer and Stejskal, were aided substantially by their generous cooperation. Vic's development of the 'bullet' MAS rotor, aided in the design stages by his observation of the flow patterns of cigarette smoke that he skillfully exhaled to strategic locations of his prototype systems, made it possible for us to venture into a variety of applications of CP MAS NMR—e.g. coal and oil shale (initially in collaboration with Fran Miknis of the Laramie Laboratory now known as the Western Research Institute).

The establishment of a federally-funded NMR Center at CSU did not happen soon enough to provide the position that Vic needed to stay in Fort Collins, so Chemagnetics, Inc. was established, with Vic and Bettie Bartuska, and Maxine and me as partners. Initially the company existed, and indeed prospered, by providing CP MAS probes (made by Vic, with help later by Robin Lewis) to JEOL for its FX-60 spectrometer. With profits from these probe sales, the company expanded its activities, technology base, and human resources (e.g., Dave Dalbow, a biologist turned magnet designer, instrumentation specialist and manufacturing ace; and David Lewis, a whiz at optimizing and implementing mechanical designs). Superconducting magnet technology was acquired initially from Craig Bradley, then extended by Dave Dalbow and Dean Sindorf, and by about 1983 the company was poised to think about building complete spectrometers. This was made possible by investments, initially from a New England group and later from family sources, and a parallel entity called Magnechem was established. With Steve Freeland developing a data system, Allen Palmer a probe, and with substantial input from Dale McKay (now at Quantum Magnetica), Dean Sindorf and, of course, Vic, the A-200 was introduced. Although not a huge success commercially, the A-200 (for which the Varian Gemini-200 eventually validated the concept) paved the way for subsequent spectrometers, mainly solids oriented—the M series, the CMC series, and the CMX series.

Chemagnetics grew during the 1980s, adding key people like Joe DiVerdi (from Opella's group) and David Hughes (from Varian). While never a resounding financial success during the 1980s, the company reached a point where 'mom and pop' financing was no longer viable (every month the bank would look at the Maciel and Bartuska homes with ever-increasing intensity). Hence, after an unsuccessful two-year search for suitable American financing, partnership, or purchase, controlling interest in Chemagnetics was sold to Otsuka at the end of 1989, and they subsequently purchased total ownership. My own role in the company had been primarily as a consultant and member of the Board of Directors, and that involvement ended a year or so after the 1989 purchase by Otsuka.

The third major development in my professional life during the late 1970s was the establishment of an NSF-funded regional instrumentation facility at CSU in October 1978. Although the CSU NMR Center was not formally part of our research group, the affiliation was close, and both entities benefited greatly from the association. Not only did the NSF funding provide exciting new facilities (spectrometers), but it also made it possible to assemble an outstanding technical

staff—initially Bruce Hawkins (who is still at CSU, as a computer specialist, and has a side business in process control NMR) as manager, Jim Frye (now at Chemagnetics), and Dale McKay (who moved to Chemagnetics in about 1985, and subsequently moved to Quantum Magnetica). The Center brought modern NMR capabilities, especially for solids, to a large number of scientists, and successfully survived competitive renewal cycles in 1982 and 1986. The staff, with Dale McKay replaced in 1985 by Chuck Bronnimann (after he finished his Ph.D. project next door), not only provided valuable service to outside Center users, but also dramatically enhanced the overall technical expertise in our laboratory and were enormously helpful to the students. When NSF funding for the Center dried up in 1989–90, because of changing NSF policies, the saddest reality that we faced was the possibility (eventually the certainty) that an outstanding team could not be kept together. Both Jim Frye and Chuck Bronnimann moved to Chemagnetics in 1991.

During the same period when the NMR Center was being established and flourishing, our research group's activities in solid state NMR were growing. A substantial effort in the area of coal and oil shale studies was under way, an effort that has involved several people during the past 17 years: Nick Szeverenyi (a postdoc, now on the faculty at the Health Science Center, Syracuse, New York), Mark Sullivan (now at Hercules), Pat Hatcher (then a graduate student at the University of Maryland, and now a faculty member at Pennsylvania State University), Larry Dennis (a postdoc, now at Exxon R & D in Texas), Allen Palmer (a postdoc, now at Chemagnetics), Richard Bryson (deceased), Gaye and Oktay Erbatur (collaborators from Çukurova University in Turkey), Mark Davis (now at the National Renewable Energy Laboratory in Golden, CO, after a period on the staff of the NMR Center), Chuck Bronnimann, Robert Wind (now at PNL, after a couple of years at Chemagnetics), Greg Quinting (a postdoc, now at Sherwin-Williams), Ming Zhang (now in the import–export business in Chicago), H. Vicky Pan, Jincheng Xiong, and Antoni Jurkiewicz (originally a Fulbright Fellow from Poland, who has been a major influence in our coal research program for several years, and recently moved to PNL).

Another area of solid state NMR application in which our efforts began in the late 1970s and continue to the present is in the study of surfaces, especially silicas and derivatized silicas. Dean Sindorf (now at Chemagnetics) was the first to demonstrate, in the silica system, how $^1\text{H} \rightarrow \text{X}$ cross polarization can be used as a surface-selective technique. Dean's extensive work on silicas, their dehydration and rehydration, and their silylation was based on the ability of ^{29}Si NMR to distinguish among $(\text{Si}-\text{O}-)_2\text{Si}(\text{OH})_2$ sites, $(\text{Si}-\text{O}-)_3\text{SiOH}$ sites, $(\text{Si}-\text{O})_4\text{Si}$ sites and $(\text{SiO}-)\text{Si}\equiv\text{R}$ sites on silicon surfaces, and was followed by related studies by several people in our laboratory, including Bruce Hawkins, Jim Frye, Steve Caravajal (now at Procter and Gamble), Walt Rudzinski (a frequent collaborator in the earlier days of these studies, from Southwest Texas State University), Bob Zeigler (now at Himont), Dave Kinney (now at ARCO), Ellen Keiter (a sabbatical visitor from Southern Illinois University), I-Ssuer Chuang, and Mike Shatlock (now at PPG, in Pittsburgh), who carried out early ^{113}Cd experiments on cadmium oxides analogous to ^{29}Si experiments on silica. I-Ssuer has been the key researcher in this area in recent years. Just as Dean Sindorf

found that ^{29}Si chemical shifts distinguish among various types of silicon sites at silica surfaces, Chuck Bronnimann, in his extensive development of CRAMPS techniques and applications, found that ^1H CRAMPS-based experiments could distinguish between hydrogen-bonded and isolated OH groups on a surface. N. R. Jagannathan (a postdoc, now on the faculty of the University of Madras) carried out some related experiments, and H. Vicky Pan and Changhau Liu are now studying some key structural issues of silica surfaces via ^{29}Si , ^1H , and ^{13}C NMR techniques.

Other surface-related NMR studies in our laboratory have been based on basic small-molecule probes of acidic surface sites. These studies have involved primarily I-Ssuer Chuang, Jim Haw (a postdoc, now on the Texas A & M faculty), Bruce Hawkins, Xiaohui Ji (now in the import-export business in Hong Kong), Laima Baltusis (a postdoc, now at Varian), and Jim Frye.

Our research group also has a long-term involvement in the application of solid state ^{13}C (and in some cases, ^1H or ^{31}P) NMR in the characterization of plant-related materials, e.g., cellulose, lignin, seeds (including germination), biomass issues, wood chemistry, and wood rotting. Participants in this work have been primarily Vic Bartuska and Dean Sindorf (our earliest efforts in this area), Dan O'Donnell (a postdoc, now at Phillips Petroleum), Jim Haw, Galen Hatfield (now at W. R. Grace), Maziar Sardashti (now at Phillips Petroleum), Mark Davis (in collaboration with Herbert Schroeder of the Department of Forest and Wood Science), and Cynthia Ridenour (now at Chemagnetics).

Scientifically intermediate, in a sense, between coal studies and plant-related studies have been a series of studies of humic and sediment samples. This work has been carried out mainly by people listed above in relationship to coal and plant-derived samples, some of it in collaboration with scientists of the US Geological Survey.

During the 1980s and 1990s, our research group has also extensively studied synthetic organic resins, principally phenolic resins, urea-formaldehyde resins, and furfuryl alcohol resins. The primary participants in this work have been I-Ssuer Chuang (throughout our work from 1982 to the present), Tom Early (a postdoc, now at GE Schenectady), Galen Hatfield, Rich Bryson, and Dave Duff (now at Varian).

In addition to the above-mentioned emphasis on solid state NMR applications to organic samples and silicas during the 1980s and 1990s, there has also been substantial NMR activity in our laboratory on inorganic systems (e.g., cadmium compounds, phosphoranes, ceramics, high- T_c superconductors, minerals) based on a variety of nuclides (e.g., ^{11}B , ^{17}O , ^{23}Na , ^{27}Al , ^{31}P , ^{89}Y , ^{113}Cd). The primary participants in this work have been Vic Bartuska (our earliest efforts), Mike Shatlock, Gary Mennitt (on sabbatical leave from Brooklyn College), Larry Dennis, Jim Frye, Steve Dec (who served on the Center staff until moving to the staff of the University of Connecticut), Bruce McGarvey (on sabbatical leave from the University of Windsor), John Fitzgerald (on sabbatical leave from South Dakota, and subsequently a frequent and valuable collaborator), Satoshi Shinozaki (on sabbatical leave from Chiba University), Paul Marchetti (a postdoc, now on the staff at the University of Arizona), and Joe Iwamiya, as well as Leonard Interrante and Wayne Schmidt (frequent collaborators from Rensselaer Polytechnic Institute).

Pervading our solid state NMR research during the 1980s and 1990s has been a continuing thread of technique development, much of it associated with mechanical developments, e.g., ultra high-speed spinning (mainly by Steve Dec, with the help of Robert Wind), and ultralarge MAS rotors (mainly by Ming Zhang), and/or gadgetry. Included in this last category are the imaginative developments of angle-flipping (the technical precursor of DAS) and magic angle hopping (the precursor of Gan's slow spinning) by Ad Bax (a postdoc here, now at NIH) and Nick Szeverenyi. The roughly two-year period between 1981 and 1983 when these two incredibly innovative individuals were here simultaneously as postdocs was a magical period for our laboratory. In and out of the laboratory, this pair was 'a couple of wild and crazy guys' (ref: *Saturday Night Live*). I have been told that Nick and Ad, both bachelors at the time, 'cut a swath' through Larimer County socially. These two were responsible for getting our group into the habit of thinking in terms of two-dimensional strategies (e.g. for determining chemical shift anisotropies) and in terms of incorporating mechanical trickery, when it is advantageous. This baptism led to later developments like the stop-and-go (STAG) technique (Bob Zeigler and Robert Wind), the slow-and-go (SLAG) technique (Steve Dec), and the GRASSHopper (gas reactor and solid state hopper, Steve Dec), as well as techniques for optimizing CP efficiency (Mazi Sardashti), and chemical shift-selective CSA determinations (Joe Iwamiya and Mark Davis). Nick Szeverenyi was also responsible for our entry into solid state NMR imaging, an area in which we have used only homebuilt equipment. This amateur (i.e. financially unsupported) effort has encompassed even MAS techniques, has yielded several publications, and has involved the part-time efforts of several group members—Mark Davis, Dave Duff, Herman Lock, Yahong Sun, Marian Buszko (a postdoc, now on the staff of the University of Florida), and Takao Shinozaki (on sabbatical leave from the KAO corporation).

Another technique in which Nick Szeverenyi was 'instrumental' in its implementation in our laboratory is dynamic nuclear polarization (DNP). This technique experienced a huge boost in our laboratory when Robert Wind came here in 1986 from Delft for about four years. Our DNP applications have included amorphous silicon, coal, chars, doped polymers, diamond films, and silicon nitride precursor materials; and DNP technique developments have included imaging and DNP in the nuclear rotating frame. The main participants, in addition to Robert Wind, have included Mark Davis, Liyun Li (on leave from the Wuhan Institute of Physics), Nick Zumbulyadis (a collaborator from Kodak), Russ Lewis, Randy Hall (now at Chemagnetics), Jan Wooten (on sabbatical leave from Philip Morris), Junji Kobayashi (on sabbatical leave from Mitsubishi Electric), and Herman Lock. In addition, there has been very useful cooperation with Chaohui Ye of the Wuhan Institute of Physics.

Our latest 'thrust' directions are: (1) the use of modern NMR techniques to study in detail the chemical fate of pollutants in soil/groundwater systems; (2) the synthesis and characterization of novel polysiloxane systems; and (3) the generation and characterization of aromatic carbocations on surfaces. The main participants to date in the first of these three areas have been Antoni Jurkiewicz and I-Ssuer Chuang, with students David Keeler and Mark Seger also involved. The second area is being investigated by Issa El-Nahhal (a Fulbright Fellow from the Islamic University of Gaza), and

Jane Yang. The third area is being studied by Ting Tao. I hope that in these, and in any other future research directions, I am as fortunate as in the past in terms of the quality of the people who have worked with me and their scientific productivity.

NOTE

*Throughout this article the mention of a person's name without an indication of some other status (e.g., postdoc or collaborator) implies that the person was (or is) a graduate student in our research group.

Biographical Sketch

Gary E. Maciel. *b* 1935. B.S., 1956, Chemistry, University of California, Berkeley, USA, Ph.D., 1960, Massachusetts Institute of Technology (MIT), USA. Postdoctoral work at MIT (with John S. Waugh), 1960–61, his first hands-on experience with NMR. Assistant professor, associate professor, and professor at the University of California, Davis, 1961–70. Professor of Chemistry, Colorado State University, 1971–present. Approx. 320 publications. Research specialties: development and application of NMR techniques, especially for solids and surfaces, and currently for environmental studies.

Mansfield, Peter: A Personal View of My Involvement in the Development of NMR and the Conception and Development of MRI

Peter Mansfield

University of Nottingham, Nottingham, UK

INTRODUCTION

I graduated with First Class Honours in physics in 1959 from Queen Mary College, University of London. I had been involved at an undergraduate level with the design and construction of an Earth's field NMR magnetometer, a project set by the then Dr. J.G. Powles (now Emeritus Professor of Physics at the University of Kent at Canterbury, England).

The success of this project led to an invitation from Jack Powles for me to join his NMR research group in order to tackle the challenging problem of pulsed NMR in solids. This work started in October 1959 and lasted the usual three year Ph.D. study period for UK students. A piece of high-power pulsed NMR equipment was constructed¹ and during the second year of my Ph.D. studies experimental results were obtained on a number of solids. The apparatus relied on an incoherent high-power anode modulated oscillator. The experiments were concerned with applying 90° rf pulses to a range of polymers in order to measure their relaxation characteristics.

SOLID ECHOES

During the course of these experiments, a second 90° rf pulse was applied and because of the fast recovery nature of the apparatus it was possible to place two 90° pulses in close sequence to within 3 or 4 μ s. When this was done an effect which looked very much like an NMR spin echo occasionally occurred following the second pulse. The signal sometimes vanished completely and the intermittent and unexpected nature of this effect created some scepticism among other students in the lab and also with Jack Powles himself. I was asked to go back and look again to make sure that the signal echo effect was not a receiver artifact due to possible transient gain changes through overloading. Since I had already satisfied myself beforehand that this was not the case, I sat down to try to fathom out the possible origin of such an effect.

The book *Principles of Nuclear Magnetism* by Abragam² had just been published in 1961 and I was struggling to understand the application of density matrix theory on which the book relied so heavily. To my surprise I found a statement in the book which seemed categorically to rule out the

possibility of a spin echo in solids, yet here in the lab I was observing something which looked very much like a spin echo. In performing calculations I convinced myself that spin echoes in solids, far from being disallowed, would indeed occur and their presence would be highly dependent on the relative phase between the two excitation pulses. This meant that with an incoherent pulse rig the presence of a spin echo would fluctuate according to the random nature of the phase shift. The calculations were presented to Jack Powles who was able to refine them, and I was later able to demonstrate unequivocally using the isolated proton pairs within calcium sulfate that we were indeed seeing a real effect which could be confirmed theoretically.³

THE AMERICAN ADVENTURE

Following my Ph.D. studies I went in 1962 to join Professor C.P. Slichter's group in Urbana, Illinois where I learned among other things about NMR in metals. It was an extremely exciting and productive period for Charlie Slichter's group since he was heavily engaged in the development of nuclear double resonance and also in pioneering relaxation time studies in the rotating frame. I was greatly impressed by the ease with which everyone in his group seemed to be able to master the intricacies of density matrix theory, a topic which had given me so much difficulty one year earlier. However, my efforts were rewarded by being able to understand very quickly what others were achieving in the lab and I found the whole experience most exhilarating.

At the back of my mind were niggling questions concerning the work that I had left behind in London, and I continued to spend time on aspects of this while working in Urbana.⁴ Of particular interest to me in that two-year period was the question what would happen if further 90° pulses were applied in a solid? Of course it was well known what would happen in a liquid from Erwin Hahn's pioneering work on the discovery of spin echoes, and also with Bloembergen, Purcell, and Pound's work, and Carr and Purcell's work using 180° pulse trains. Unfortunately the facility in Urbana was not sufficiently powerful or sufficiently well developed to study or even see responses from the short 90° pulses so this work had to wait until I returned to England.

MULTIPULSE EXPERIMENTS

In 1964 I joined the University of Nottingham as a lecturer in Physics. I was fortunate to attract a research student immediately and together with an SRC grant was able to design and build a high-power pulsed NMR spectrometer which had the capability of producing sustained rf pulse trains. The research student who joined me was Donald Ware who had decided to come to England from UBC where he had received an M.Sc. in NMR under the supervision of Basil Dunell. Within a year or so we had built a pulse rig and obtained some of our first results. In particular we had tried sustained 90° pulse trains and to our surprise and delight had observed an effective lengthening of the FID in calcium fluoride. I was bursting with excitement to announce this and prepared a draft letter for publication in the journal *Physics Letters*.⁵ During

this time my ex-supervisor, Jack Powles, visited Nottingham (I believe as a colloquium speaker) and was able to see the effect on our machine. I remember that he looked pensive and said that he thought he had seen something very similar when visiting John Waugh's lab recently at MIT. I was, of course, unaware of any other activity in the field and nothing had been published so we went ahead with our paper which was published shortly after Ostroff and Waugh's paper on the same subject. This was in 1965 but began a period of sometimes stormy and acrimonious rivalry between me and John Waugh. This rivalry continued through the 1960s to the early 1970s and covered an extremely productive period from both the Nottingham and MIT groups, leading to generalizations of the multipulse line-narrowing theory of solids as we called it and the development of sophisticated pulse sequences such as the MREV-8 sequence which is still used today.^{6,7} Incidentally, the MREV stands for Mansfield, Rhim, Elleman, and Vaughan. In fact Bob Vaughan's group in Pasadena rediscovered the eight-pulse sequence some two years after it was first described by me in the *Journal of Physics*.⁸ Nevertheless, Bob Vaughan made some important contributions to the development of the subject and to the understanding of some of the intricacies in applying such techniques. The new rivalry with the Pasadena group was very much a gentlemanly and friendly one. It was therefore with great shock and sadness that we learned of Bob's untimely death in 1980 due to an aircraft crash at O'Hare Airport in Chicago.

Other Nottingham names associated with the development of multipulse techniques in this period were former research students Ken Richards, Dennis Stalker, Martin Orchard, Peter Morris, and Peter Grannell.

HOLE-BURNING EXPERIMENTS

Another episode which was later to have a bearing on the development of magnetic resonance imaging at Nottingham involved a research project funded by the Royal Radar Establishment at Malvern. This involved Raymond Andrew as cosupervisor with Alwyn Finney as our research student. We had been asked to look into the possible application of NMR as a means of information storage. The path that we chose to follow involved resurrecting some ideas on information storage originally proposed by Erwin Hahn, which relied upon hole-burning experiments in inhomogeneously broadened lines in liquids. Amongst other things we proposed and tried storing pulse trains by the simple mechanism of irradiating a suitably broadened liquid line with the pulse train, then reading out the information using a swept CW technique which revealed as hoped a hole-burnt spectrum which was close in shape and spacing to the Fourier transform of the pulse train spectrum. The line broadening in this work was achieved by applying a linear magnetic field gradient. This work was started in 1966 and a final report submitted in 1969.⁹ The ideas developed in this project were to play an important part in my thinking later on after I had conceived the idea of NMR imaging which I now relate.

NMR IMAGING: THE IMMACULATE CONCEPTION

In 1971 I made plans to spend a sabbatical year in Heidelberg working in Karl Hauser's group. He had recruited Ulrich Haerberlen from John Waugh's lab to set up a multipulse facility. Meanwhile at Nottingham, Allen Garroway, formerly from Bob Cotts's group in Ithaca joined my group as a postdoc to learn about multipulse experiments in solids. The plan was that he would run my group during my absence. He became heavily involved in the implementation of fast Fourier transforms and during the course of the winter of 1972 together with Dennis Stalker produced some nice results in a number of fluorinated solids showing chemical shift anisotropy. The line-narrowing capability of the homebuilt spectrometer (constructed by Terry Baines) allowed effective linewidths down to 5–10 Hz in calcium fluoride and was something of a record at the time.¹⁰

In May or June 1972, while discussing our results with Allen Garroway and Peter Grannell over a cup of coffee the question arose as to what other possibilities there were to utilize the line-narrowing capability of the spectrometer. What followed was greatly influenced by work I had been doing on the calculation of lineshapes in solid calcium fluoride.¹¹ During this work I had been greatly impressed by a paper on Green's functions by Tomita and Tanaka¹² who had applied the technique to calculations in ferromagnetism. I was attempting to use a similar analytical approach and was intrigued by their use of spatial Fourier transforms of the dipolar interaction terms. I had been thinking how nice it would be if the spatial terms in the dipolar interaction could be unraveled to yield the lattice constants. This was of course a pipe dream in that particular context. However, during this coffee discussion it suddenly clicked in my mind that by applying a linear field gradient to a solid in which the dipolar interaction had, in effect, been removed we could achieve spatial Fourier transformations in solids, thereby evaluating the internal structure of a solid. My recollection is that Allen was somewhat sceptical and Peter Grannell was more receptive to the idea. In any event, I went away to perform some simple calculations and gave a copy of these to Peter Grannell and suggested that we might mount some simple experimental evaluation of the idea in a model lattice system. Unfortunately he was approaching the end of his three-year Ph.D. research period and was naturally more concerned about finishing off his research on time. The idea therefore languished during the summer of 1972. I was also making preparations to depart for Heidelberg.

SABBATICAL IN HEIDELBERG

My arrival in Heidelberg in October 1972 saw the start of an intense period of regular correspondence between me and Peter Grannell, and to a lesser extent with Allen Garroway. I was anxious that Peter should press on with the imaging experiments now that he had completed his Ph.D. studies. By November 1972 he had made some progress which he casually mentioned to Raymond Andrew during the autumn term of 1972. Peter slowly made further progress in 1973 to the point where he had demonstrated NMR diffraction effects in a model one-dimensional lattice. I returned to Nottingham in July 1973

and promptly wrote up the work as a letter for the *Journal of Physics*.¹³

PRESENTATION IN KRAKOW

I had already submitted an abstract for my invited talk at the 1st Specialized Colloquium AMPERE which was to be held in Krakow, Poland in September 1973. This abstract¹⁴ included a description of the one-dimensional imaging experiments. So far as we were concerned, my subsequent announcement of NMR diffraction in Krakow would be the first mention of this novel effect. At the end of my presentation, John Waugh, who was in the audience, said something to the effect that he thought that what I had just described was similar to a proposal by Paul Lauterbur. I did not know Paul Lauterbur at that time and was unaware of any similar work that he may have done. I was of course intrigued by Waugh's comment and as soon as we returned to Nottingham I looked up Lauterbur's paper.¹⁵ I was struck by the stark contrast between our two approaches to NMR imaging. In my pulsed approach I had formally proposed the optical analogy of plane-wave scattering through a mathematical framework where reciprocal lattice space or k -space was introduced and in which the k vector was proportional to the product of time and gradient vector. The concept of k -space in MRI, of course, plays an important role these days in categorizing different imaging sequences in terms of the k -space trajectory.

SLICE SELECTION

My involvement with the development of MRI continued in 1974 with the introduction of rf slice-selection techniques.¹⁶ This work was done in collaboration with Allen Garroway and Peter Grannell. I had come to the conclusion that rf pulses in combination with switched linear gradients could be used to define an active slice of magnetization within a larger specimen based on the experience gained in the late 1960s with Alwyn Finney's work. Allen Garroway had independently arrived at a similar conclusion influenced by a paper by Tomlinson and Hill,¹⁷ in which frequency selective pulse sequences were proposed for irradiating inhomogeneously broadened spectral lines for spin decoupling experiments. Allen's approach was, therefore, to concentrate on pulse sequences comprising short constant amplitude high-power pulses with variable pulse spacing and rf phase. We quickly realized that the easier and cleaner approach to slice selection was simply to modulate a continuous rf pulse, the modulation being designed to create a nearly rectangular slice of active spin magnetization.

We quickly adapted tailored rf excitation methods to produce a fast line-scan imaging technique. This was used by Andrew Maudsley to produce the first NMR images demonstrating live human anatomy, albeit on one of his fingers.¹⁸

ECHO PLANAR IMAGING

In 1976 I introduced the ultra-high-speed echo planar imaging technique.¹⁹ This arose out of a growing concern of

mine at the time that if NMR imaging were ever to be of clinical value, imaging times, then measured in many tens of minutes, would have to be drastically reduced. At the time of its conception EPI was difficult to implement by virtue of the extreme requirements of gradient amplitude and fast switching rates. Nevertheless, an early version of EPI was implemented by Ian Pykett in 1977.²⁰ He succeeded in obtaining crude snapshot images of a test-tube phantom and later a live human finger. With the benefit of hindsight, it is clear to see that EPI and the whole concept of ultra-high-speed imaging and spectroscopic imaging were ahead of their time by some 15 years or so.

Except at Nottingham, EPI languished worldwide but received a slight impetus when Ljunggren published his paper in 1983 on the comparison of NMR imaging methods using the rediscovered k -space approach.²¹ By then the major MRI companies had launched a series of medical scanners based on slower imaging methods and were clearly not of a mind to upgrade machine specifications for the implementation of EPI before recouping their investments. Thus it was that EPI languished for a further 10 years.

In this intervening period, newcomers to the business began to rediscover low rf angle techniques and applied them to the process of speeding up the slower MRI methods. This class of fast imaging, known as FLASH imaging, was preferred by manufacturers who saw it as a stepwise approach to the implementation of high and hopefully ultra-high-speed imaging.

Also, in this intervening period, two former research students of mine, Ian Pykett and Richard Rzedzian, emigrated to the USA and formed a company in Boston called Advanced NMR Systems with the object, according to the company's prospectus, of building and marketing an EPI machine. Although several prototype machines were produced and installed at various sites, EPI never really took off in a big way commercially during that period.

ACTIVE SCREENING OF GRADIENT COILS

Back at Nottingham in the mid-1980s, we acquired a superconductive 0.5-T whole body magnet. It was clear to me, even before we received the magnet, that if EPI were to function correctly within the close confines of the magnet, something had to be done to decouple the rapidly switched gradient fields from the metal structures comprising the magnet cryostat. Work started on gradient screening in 1984 and culminated in the concept of active magnetic screening during the course of 1985.^{22,23} Active magnetic screening of gradient coils was quickly taken up by General Electric and other major manufacturers, and now forms part of the standard range of features offered on all imaging machines.

The solution of gradient decoupling has had other benefits, especially with regard to magnetic resonance spectroscopy. The fact that active screening forms an integral part of modern MR imagers has, I believe, also helped in bringing to fruition the launch of commercial EPI machines announced in November 1993 by General Electric and by Siemens.

ACTIVE ACOUSTIC SCREENING OF GRADIENT COILS

Having solved the magnetic coupling problems associated with rapidly switched gradient coils, we were soon faced with another potentially hazardous situation when trying to implement EPI or indeed echo volumar imaging (EVI) at 3.0 T. This new problem arises from the very large levels of acoustic noise emitted from the gradient system when being pulsed with the very high current levels and fast switching rates associated with EPI and EVI. Some degree of acoustic attenuation can be provided by the use of ear defenders but similar protection cannot easily be provided for animal studies or indeed for human fetal studies in utero.

These considerations have therefore led us to introduce an active acoustic screening strategy,²⁴ which tackles the source of the acoustic problem rather than treats the symptoms. Active acoustic screening can also be combined with active magnetic screening and we predict that this approach will be widely adopted in the design of future scanners.

The reduction of acoustic vibrations in the probe assembly will also confer advantages in biological and nonbiological NMR microscopy performed at very high fields. In such situations, probe movement can vitiate the achievable spatial resolution. Active acoustic screening will help to reduce this kind of induced motion artifact.

Maraviglia, Bruno: A Personal Perspective about NMR Evolution

Bruno Maraviglia

Università di Roma 'La Sapienza', Rome, Italy

'LA SAPIENZA', ROME (1962–68): QUANTUM FLUIDS

My introduction to NMR came after an important period of research on superfluid helium. After obtaining my initial degree at the University of Florence, in 1962 I joined Giorgio Careri's group which had been carrying out attractive investigations in low temperature physics at 'La Sapienza' since 1960. Being thoroughly involved in quantized vorticity by means of second sound¹ and ionic currents,² I came across experimental NMR via friends who were searching for the expected phase transition in ³He using nuclear susceptibility measurements; this transition was destined to be discovered about 10 years later at Cornell University³ via an NMR experiment whose role, in my opinion, is wider than currently believed. I will come back to this point later.

DUKE UNIVERSITY (1969–70): QUANTUM SOLIDS

At the beginning of 1969 I went on leave, as a NATO Fellow, to the Physics Department of Duke University where I was appointed Assistant Professor of Optics and Spectroscopy. The invitation came from Horst Meyer and, although not planned in advance, determined my transition to NMR. In fact, when at Duke, I had time to decide whether to join the research activities of Henry Fairbank on superfluidity or that of Horst on quantum solids. By choosing the fascinating field of solid hydrogen, I also satisfied my attraction towards NMR whose role in condensed matter was continuously growing.

I started working with Fred Weinhaus (Ph.D. student) on solid D₂, which has a slower *ortho*–*para* transition rate than H₂ in addition to the possibility of observing the $J = 0$ molecules by NMR ($I = 0,2$), which cannot be detected in H₂. After constructing a ³He cryostat, a systematic series of 'Pake doublets' of the antiferrotational cubic phase was measured at different temperatures and *ortho*–*para* concentrations. The first 'surprise' was that the $J = 0$ molecules also become ordered, with an order parameter which is about 1/10th that of the $J = 1$ molecules;⁴ the second result was the accurate determination of the zero point motion of the rotational angular momentum in a pure $J = 1$ system, together with the orientational order parameter as a function of the *ortho*–*para* concentration.⁵

Longitudinal relaxation times were also determined both in solid and liquid D₂. Liquid measurements showed complete decoupling of the $J = 0$ and $J = 1$ molecules providing a composite signal with two relaxation times, substantially different at $T_1 \sim 50$ ms ($J = 1$) and $T_1 \sim 3200$ s ($J = 0$), with a concentration $\sim 98\%$ of $J = 0$ molecules. This is probably

the widest (and the most tiring) range of relaxation times in a pure liquid.⁶

'LA SAPIENZA', ROME (1971–76): QUANTUM SOLIDS AND LIQUIDS

On returning to Rome my plans were first to establish an NMR lab in order to carry on research on quantum solids and, at the same time, continue collaboration with Horst Meyer, and secondly I hoped that my deep interest in biophysics would generate some new research line. Although a pulsed Bruker spectrometer was obtained only in 1973, in the meantime research on superfluid helium was still carried on.⁷

Solid CH₄ and solid CH₄/Kr mixtures were the quantum systems studied. The first librational band of the ordered CH₄ molecule was measured,⁸ from a study of relaxation time, and found to be in agreement with the theoretical prediction.⁹ Disorder of the CH₄ ordered sublattices was also investigated as a function of Kr concentration and in relation to spin conversion.¹⁰

UNIVERSITY OF BRITISH COLUMBIA (1977–78): BIOLOGICAL MEMBRANES

The results of Myer Bloom's group in Vancouver had reconciled biological subjects with a quantitative physical approach and this attracted me so much that I decided to join his group in Vancouver.

Intense activity, aimed at the structure and dynamics of membranes, was going on at the University of British Columbia with excellent interaction between NMR physicists and biologists. In view of the fact that the erythrocyte membranes provided systems which had been studied extensively and that they play an important role in their structural correlation with diseases, I proposed to start research on such membranes. The results obtained with the crucial contribution of Jim Davis, allowed us to conclude that the erythrocyte membrane has a very wide thermal range of fluidity.¹¹

On returning to Rome I finally determined to continue work on the physics of biological systems, including the use of spatially resolved NMR, which seemed well suited to the study of heterogeneous living organisms.

'LA SAPIENZA', ROME (1979–PRESENT DAY): SPATIALLY RESOLVED NMR

I had carefully followed the 'birth' of NMR imaging in the early 1970s mainly as an outsider since my direct involvement only began in 1979. In fact among the general skepticism (until 1980) regarding the possibility of producing quality images, there were frequent dramatic arguments as to who was the 'inventor' of NMR imaging. At this point I would like to remark on one experiment which anticipated the work of Paul Lauterbur¹² and Peter Mansfield and P. K. Grannell¹³ in this field. This important publication, which I have already mentioned³ for its important discovery of the magnetic and statistical properties of ³He, produced, with the help of a linear

magnetic gradient, a one-dimensional image (they called it a profile) of a heterogeneous sample containing both solid and liquid ^3He . The authors also clearly expressed (on p. 921) the logic of selective irradiation, widely used today in NMR imaging. This paper was published before any other now currently regarded as NMR imaging work. Personally, from a knowledge of the authors of that work and the great impact of their discovery for the physics of condensed matter, I believe that they considered their imaging procedure a 'trivial tool'. Of course this is not meant to detract from the importance of the clear-cut thinking of Paul Lauterbur on this subject, who through the use of the projection reconstruction method demonstrated the way to produce images of biomedical interest.

The work on NMR imaging at 'La Sapienza' began in 1979 with the aim of building a small size imager as a first prototype. Close collaboration with Nottingham, i.e. with Raymond Andrew and Peter Mansfield, and frequent exchanges with Paul Lauterbur, gave us experience in the several approaches to imaging which were being tested at that time. In early 1981 the prototype was operating¹⁴ and a whole body machine was immediately planned. The whole body system produced its first spin warp images in early 1982. The role of Francesco De Luca and Francesco Vellucci in this project was crucial. In fact, Vellucci later moved to Esaote Biomedica with others to start industrial production. My collaboration with Esaote is still active today. More fundamental aspects were then investigated such as the maximum entropy approach to NMR imaging¹⁵ and some line-narrowing procedures which would lead to the imaging of solids.

Our studies of the development of NMR imaging of solids began in 1985 in connection with the work which Mefed and Atsarkin had been undertaking since 1977.¹⁶ Although the initial results were promising¹⁷ some fundamental improvements were obtained first by introducing a spin echo imaging sequence at audiofrequency in the rotating frame¹⁸ and later by using an indirect rotating frame imaging approach.¹⁹ The contribution of Francesco De Luca in this field was fundamental.

Another important subject of interest was functional imaging, which we studied using an original double resonance procedure²⁰ which allows indirect imaging of nucleus A, J coupled to proton P, with a gain in signal-to-noise of about $(\gamma_P/\gamma_A)^{11/4}$. The contribution of F. De Luca and R. Campanella in this field has been quite important.

In vivo spectroscopy²¹ and other research lines closer to medical applications have also been developed²² in collaboration with M. A. Macri and C. Cametti.

Margulis, Alexander R.: How NMR was Started at the University of California, San Francisco (UCSF)

Alexander R. Margulis

University of California, San Francisco, CA, USA

The year was 1975. During the postgraduate course given by the UCSF Department of Radiology at the Fairmont Hotel in the middle of March, several presentations dealt with computed tomography of the brain with the wondrous EMI CAT scanner. Dr. Leon Kaufman, a physicist in our nuclear medicine section, who had been spending much of his energy on creating the germanium camera for nuclear medicine, asked for a one-half hour appointment on September 3, 1975. What he presented that day sounded extremely challenging. Get involved in developing and exploring a new technique of imaging: nuclear magnetic resonance. He drew on a piece a paper that he picked up from my desk a sketch outlining the basic physics of this approach. It all sounded mystifyingly complicated, particularly when he described how the signal caught by the receiving coil worked similarly to CAT scanners to produce images. Asked how good they were, he answered that they were not very good as yet but there was tremendous potential for improvement. I feel and felt strongly that the function of radiologic research is to bring physicists, engineers, radiobiologists, physiologists, clinical specialists, and radiologists together to develop the best imaging approaches that will depict the normal and abnormal anatomy and physiology of the body and its organ systems. The ultimate goal, perhaps unachievable, is to obtain as much information as possible at the level of basic biochemistry.

Leon was much more conservative in his expectations, but nevertheless, quite enthusiastic about the potential of this new imaging approach. He told me that a professor at Berkeley, Dr. Jay Singer, was a pioneer in research in this discipline and was willing to help us. I asked what I needed to do to help Leon get started; he suggested the sum of \$40 000 to borrow a magnet, install it, and hire a young scientist with NMR experience. The meeting concluded with my promise to help. The next day, September 4, 1975, I received a hand-delivered letter which is reprinted here in its entirety.

‘September 4, 1975

Dr. Alexander Margulis
Department of Radiology
380-M

Dear Dr. Margulis:

Following our conversation to the effect, I would like to propose that we initiate an active research program leading to the development of a diagnostic imaging technique using nuclear magnetic resonance (NMR).

Briefly, the principle of NMR involves the following: all odd mass number atomic nuclei (those with an even number of protons and odd number of neutrons, or vice versa) behave as if they were small magnets. Placed in an external magnetic

field they will align their spin with the field. The spin direction (or axis of rotation of the nucleus) can be flipped or turned around with radio waves of an exact energy. In returning to the normal state the nucleus will radiate back these radio waves. The energy of radiation, or wavelength, will depend on the nucleus being flipped as well as on its chemical state. The location of the radiating spot can be determined by purely electronic scanning (no physically moving parts). The potential thus exists for imaging the chemistry of the body. Since hydrogen is the most abundant odd mass number nucleus in the human body (naturally occurring O, C and N are almost fully even mass number nuclei), the easiest thing to do with NMR is to map the H density. Notice that this differs from electron density as measured by the EMI scanner. Also notice that while the EMI scanner needs information from *all* parts of the scanned region to resolve density by mathematical reconstruction techniques, the measurement of H density is unique at each spot. Thus, motion and algorithm artifacts become much less serious in NMR.

The second thing that can be done is to differentiate H in water from H in other tissues, thus obtaining a water map. Furthermore, blood can be differentiated from muscle, leading to the possibility for measuring myocardial and brain perfusion, two vexing clinical problems on which we have little or no diagnostic handle. More intriguing yet, we could possibly measure the chemical state of the H, maybe finding areas where certain fats accumulate, or where radicals are present. Also, certain atoms may be differentiated. For instance, phosphorus is known to strongly label any area of increased cell division. Natural P has an odd mass number and is detectable by NMR. Although natural calcium is mostly of even mass number, some is odd. Maybe calcifications (even diffuse ones not seen in X-rays) can be localized by NMR.

Clearly the payoffs are large, but the risk of failure is commensurate. For us to enter this area of research now will be extremely timely. I have found out that similar research is ongoing at Brookhaven, but this should not discourage us. There is an analogy with the germanium camera work, where we entered a technically difficult research area that was being studied in three other institutions. Thanks to the quality of the groups we are collaborating with, we managed, in less than two years, to become leaders in the field. In a similar vein, we learned a lesson from the search for support of the germanium camera: we were turned down three times because of skepticism as to our expertise and ability to solve this problem. After the School of Medicine, Academic Senate, grant tailings, and Livermore groups seeded the project and initial results were presented, funding was obtained for it.

The disadvantages of going to the NIH for funding at this time are two-fold. We will likely be turned down for lack of track record, and it will take a year to find out that we were turned down. I would propose that we proceed as follows:

1. Establish collaborative ties with an expert group. I have been directed to Professor J. Singer of the EE Department in Berkeley. He has an impressive publication record in the field, a long standing interest in biomedical applications (including a collaborative project with the obstetricians on this Campus), and is interested in collaborating with us.

2. Hire, for a year, a full-time researcher with experience in NMR, offering an Adjunct Assistant Professor position. Dr. Singer has recommended a recent Ph.D. student of his who

knows both the technique and the equipment, and who is able to build some of the specialized equipment himself.

3. Borrow, for a year, some of the most expensive equipment needed (magnet and power supply) and obtain appropriate space on Campus for this work. The size of what we can image depends on the magnet, but the larger the magnet the more the constraints on space. There are magnets at the Lawrence Berkeley Laboratory with useful areas as large as 29×36 in, but they weigh 50 000 lb and it may take six months to obtain good regulated power for them. A magnet with a useful volume of many cubic inches could be borrowed from Dr. Singer and put into operation quickly. We will get what we pay for. We should probably plan for both approaches simultaneously, so that we may get immediate results and look at the long term as well.

4. We need \$20 000 for specialized major components. Dr. Singer estimates that this is reasonable for what we are trying to do.

5. We will also have to shift to this project (on a part-time basis) some of our research personnel and facilities.

I wish to emphasize that you should look at this as a poor risk loan. At worst, we will have lost \$40 000 (note that a scintillation camera sells for \$70 000, and EMI scanners are bargains at \$400 000–\$700 000 a piece). If things go well this investment will return the amount many times over. It is a gamble, but we have to look at diagnostic radiography not only in terms of the next year or two. Rather, we now have to lay the foundations for the next 10 years. I have no qualms that we are doing this in nuclear medicine, but it is clear that in the field of x-ray diagnostic developments we are lacking in hardware innovation. We have now a chance to provide a significant contribution.

Sincerely,

Leon Kaufman, Ph.D.'

I took \$20 000 from the departmental professional fund reserves and obtained a loan for another \$20 000 to be repaid when possible from the UCSF School of Medicine, Dean Julius Krevans. Julie emphasized that he had faith in Leon Kaufman. Leon proceeded and kept me informed about the progress of the project. Dr. Thomas Grover was hired to start the project and a small core magnet was bought and installed in the Earl Miller Laboratory in the basement of the East Tower Research Building on the UCSF campus. Dr. Grover moved soon to Colorado and the program really started going with Lawrence Crooks who had obtained a Ph.D. with Dr. Jay Singer at the University of California, Berkeley. As another \$50 000 was needed to proceed and pay for Larry and the freshly purchased 0.35 T-0.30 cm core magnet, Leon, through a friend, negotiated an arrangement with Pfizer Medical Systems for a matching grant of \$25 000 to proceed with the project. The first image of a rat's heart was published in 1978.¹ From then on the images got better and better and Larry, Leon, and I decided that it would be important to learn as much as possible about correlating imaging techniques to anatomy and physiology. A number of papers resulted reporting the application of Hahn's spin echo sequence into imaging, obtaining what is now called T_1 , T_2 , and proton density weighted images.² A

correlation of frozen rat slices with corresponding MR image slices was published in another article in 1980³ as also was a paper on the physiological applications of NMR imaging showing what was later called the 'flow void' by comparing the image of the aorta and the IVC in the living with that of the dead rat. An editorial that I wrote to accompany these articles in *Radiology* stated that we have a new technique which will revolutionize radiology. It was rejected as being too optimistic. Pfizer ordered for what now is the Radiologic Imaging Laboratory (RIL), housed at Oyster Point, a 0.35 T large core cryogenic magnet from Oxford Magnets which arrived in early 1981. While animal experiments continued on the small magnet teaching us about the MR imaging properties of implanted rat tumors⁴ and inflammatory diseases,⁵ we started imaging volunteers. We were fortunate to obtain, after many false starts, images of high quality just as Pfizer decided to get out of the imaging business and the new subsidiary of Diconics, NMR Diconics, was formed with venture capital investors. Another fortunate incident was obtaining the first body images on a volunteer with Dr. Kaufman who filled the body coil, rather than with the slender Dr. Crooks. The excellent multislice images of the head and abdomen produced universal admiration at the 1981 Radiological Society of North America meeting. The year 1982 saw the formation of the Society for Magnetic Resonance in Medicine by a small group composed of Drs. Lauterbur, Pohost, Budinger, Chance, and myself. The first meeting in Boston, incidentally a smashing success, had a number of clinical papers presented based on cooperative work between basic scientists, engineers and subspecialists in radiology at UCSF. This started the era of radiologic subspecialties in MR imaging.

Marshall, Alan G.: Ion Cyclotron Resonance Mass Spectrometry: a Brief History

Alan G. Marshall

Florida State University, Tallahassee, FL, USA

How does an NMR spectroscopist end up in mass spectrometry? When I joined John Baldeschwieler's research group at Stanford in 1965, he had just acquired the first commercial ion cyclotron resonance mass spectrometer from Varian. He realized that both NMR and ICR could be performed by marginal oscillator detection of power absorption at constant frequency and swept magnetic field, and his original intent was somehow to apply to ICR the NMR double resonance techniques (see below) which he had recently comprehensively reviewed.¹ My own Ph.D. research began with theoretical and experimental analyses of the NMR of quadrupolar halide nuclei as probes of accessibility and flexibility of specific mercury-labeled sites on chymotrypsin.^{2,3} However, once immersed in a research group populated by several ICR mass spectroscopists, I soon began to notice parallels between the two techniques, and was able to show how to extract ion–molecule reaction rate constants from ICR lineshapes.^{4,5}

Melvin Comisarow joined Baldeschwieler's group as a postdoc during my last year there as a graduate student. I left for a faculty position at the University of British Columbia in 1969 and Comisarow joined me there two years later (also as a faculty member). Mel spent the next two years building a field-scanning continuous wave ICR instrument, and in 1973 we collaborated in the invention and reduction to practice of Fourier transform ICR (see below). I maintained an active role in NMR until the late 1980s⁶ and am now concentrating exclusively on FT-ICR mass spectrometry.

Pulsed excitation with Fourier transform data reduction is not the only common feature of NMR and ICR. In fact, there are ICR analogs to the following NMR phenomena: Larmor precession, T_1 , T_2 , rotating frame, sample spinning, spin lock, adiabatic rapid passage, Bloch equations, 180° pulse, double- and multiple-quantum coherences, shaped and stored waveform pulses, correlation NMR, crossed-coils versus single-coil modes, B_0 shimming, B_1 shimming, chemical exchange, population transfer, nuclear Overhauser effect, phase encoding by time delay, two-dimensional NOESY, T_1 noise, Hadamard excitation, phase cycling, dipolar versus quadrature excitation/detection, spinning sidebands, spin echo, dispersion versus absorption, various mode-coupling effects, direct versus heterodyne detection, decoupling, spin tickling, double resonance, and laser CIDNP. Finally, although ICR is usually analyzed classically, there is an alternative formalism based on cyclotron energy quanta. I shall now present a brief historical introduction to ICR, in the hope that at least some of its common heritage with NMR will be apparent.

In the absence of an electric field, an ion of mass m and charge q moving at velocity v in a plane perpendicular to a homogeneous static magnetic field $\mathbf{B}$ executes a circular

Figure 1 Schematic representations of the principle of operation of three devices based on the cyclotron principle. Left: cyclotron accelerator: each time an ion passes between two D-shaped electrodes, an electric field pulse (produced by alternately charging the electrodes to high voltage) speeds up the ion, which on entering the other D-electrode travels at the same cyclotron frequency but at larger cyclotron radius. Top right: omegatron, in which ions are accelerated continuously to larger cyclotron radius until they strike a collector electrode. Bottom right: power absorption measurement (with a marginal oscillator) during simultaneous resonant excitation; a mass spectrum is obtained by slowly varying the magnetic field at fixed excitation/detection frequency

motion of radius r at a 'cyclotron' frequency ω_c :

$$\omega_c = \frac{v}{r} = \frac{qB}{m} \text{ (SI units)} \quad (1)$$

The first of many clever methods and uses for exciting and detecting such motion was the invention and development by Lawrence and Livingston of the cyclotron accelerator in the early 1930s.⁷ Ions were accelerated by electric field pulses, timed to coincide with the passage (twice per cyclotron orbit) of an ion packet between two D-shaped electrodes [Figure 1(left)]. The history of the cyclotron accelerator development era is summarized in a recent book.⁸

The first 'chemical' cyclotron designed to detect (rather than simply accelerate) ions according to their mass-to-charge ratio, m/z (in which m is ion mass in u and z is the number of elementary charges per ion) was the 'omegatron' developed by Sommer and Hipple in about 1950 [see Figure 1(top right)]. Their device used resonant excitation produced by applying a *continuous* (rather than pulsed) spatially uniform differential rf voltage between two opposed flat electrodes to excite ions in an orbit of increasing radius (i.e., a spiral path); the resonantly excited ions were detected by the current produced when the ions eventually struck a collector plate. A small dc potential was also applied to prevent ions from escaping along the $\mathbf{B}$ direction.

The next major innovation was, by analogy to NMR, detection of cyclotron motion by use of a marginal oscillator to measure *power absorption during excitation* [see Figure 1(bottom)], based on slowly scanning the applied magnetic field strength at fixed frequency for excitation and detection.

This idea seems to have been developed independently in the early 1960s by Leont'ev in Russia as a device to measure magnetic field strength⁹ and by Wobschall in the USA as a mass spectrometer.^{10,11} In the first commercial version developed by Llewellyn, an additional dc voltage was applied to induce the ions to drift from the ionization region (where the presence of a continuous electron beam disrupts attempts to excite and detect the ions directly) into a second region for resonant cyclotron excitation and detection.¹² Interestingly, in a paper largely unknown to most others in the field at the time, Genequand conceived and demonstrated excitation on one pair of opposed plates and (simultaneous) detection on an orthogonal pair of opposed plates, in the same spirit as 'crossed-coils' excitation and detection in continuous wave NMR of the 1960s.¹³

'Chemical' applications of ion cyclotron resonance (ICR) may be said to have begun with the Stanford group's introduction of what they called 'double resonance' (again by analogy to NMR), in which 'parent' ions of one m/z ratio were excited to higher kinetic energy, leading to ion–molecule reactions which were rendered observable by detection of a change in the abundance of 'product' ions of a different m/z value.¹⁴ This general approach, now generally known as 'MS/MS' or 'tandem' mass spectrometry,¹⁵ is one of the most powerful analytical tools for the analysis of mixtures, determining ion structure, and identifying ion–molecule reaction pathways, kinetics, equilibria, and energetics.

Figure 2 Schematic representation of a Fourier transform ICR mass spectrometer. Top: a small packet of ions is excited out to a particular cyclotron radius. Bottom: the excitation is removed, and the coherently orbiting ion packet induces a charge on opposed detector electrode plates; that time domain current signal is converted to a voltage, digitized, and Fourier-transformed to yield a frequency domain spectrum which is then converted to a mass spectrum

As for carbon-13 NMR, the advance which made ICR feasible for a wide range of applications was the introduction by Comisarow and Marshall in 1974 of pulsed¹⁶ and frequency sweep (chirp)¹⁷ excitation, followed by broadband detection of an induced transient signal (see Figure 2), followed by Fourier transformation (FT) to yield the whole mass spectrum in the time formerly required to scan through a single peak.¹⁸ The FT experiment made it possible to obtain a full-range mass spectrum in ~ 1 s compared with ~ 0.5 h with scanning instruments. A typical experimental event sequence (~ 1 s) for the study of ion–molecule reactions is shown in Figure 3, along with the more familiar names given to the corresponding condensed-phase experiments. Because the magnetic field was now static rather than swept, magnetic field homogeneity was much improved and because detected ions traveled in a circle (like spinning the sample in NMR¹⁹) rather than a spiral (as in prior instruments), the mass resolving power improved (by a factor of up to 10^6).

Since FT-ICR frequency-domain linewidth varies directly with ion–neutral molecule collision frequency²⁰ (which in turn varies directly with gas pressure), FT-ICR excitation/detection is best performed at low pressure ($\leq 10^{-8}$ torr). However, most methods for ionizing neutral molecules require high pressure (up to atmospheric pressure of ~ 760 torr in some cases). In such cases, it has proved useful to perform the ionization and excitation/detection functions in chambers separated by a 'conductance limit' with a small (~ 2 – 3 mm diameter) hole to allow ion passage. The chambers may both be in a strong magnetic field (Littlejohn and Ghaderi's 'dual-trap'²¹), or the ion source may be outside the magnet, with ions guided into the excitation/detection region by rf²² and/or dc.^{23–25} electric lenses or as a highly collimated beam from a supersonic jet expansion.²⁶ Internal and external ion sources have allowed for FT-ICR mass analysis of ions formed by virtually any technique: electron ionization, chemical ionization, laser desorption/ionization (matrix-assisted or not), field desorption, fast neutral beam, glow discharge, fast atom bombardment, ²⁵²Cf plasma desorption/ionization, surface-induced dissociation, fast ion bombardment, electrospray.²⁷

Figure 3 Generalized FT-ICR experimental event sequence for study of ion–molecule reactions (left), corresponding to similar condensed-phase chemical manipulations (right)

Optimal ICR performance demands spatially uniform static and rf electric field. The static electric ‘trapping’ field may either be shimmed to zero by use of grounded screens²⁸ or to near-perfect quadrupolar symmetry with segmented electrodes.²⁹ The rf electric field may be shimmed to near-perfect uniformity with guard rings.^{30–32} It is also now possible to linearize *both* excitation and detection (i.e. eliminate harmonics and sidebands) by exciting and detecting with the same array of segmented electrodes.³³

Unlike NMR, ICR detection (even without rf shimming) is quite linear (i.e. amplitude of response is proportional to amplitude of excitation); Marshall et al. therefore were able to show that one could synthesize any desired excitation versus frequency profile by performing a discrete inverse FT to generate the corresponding time domain waveform (stored-waveform inverse FT, or SWIFT³⁴). SWIFT excitation allows for highly selective broadband mass-selective excitation and ejection (by exciting ions to a radius so large that the ions strike the sides of the container and are lost), for (for example) isolation of ions of particular m/z value(s) from a mixture or even two-dimensional (Hadamard/FT³⁵ or FT/FT³⁶) experiments for MS/MS multiplexed with respect to both parent ion and product ion masses.

The addition of a (typically quadrupolar) electrostatic trapping potential (to confine ions and prevent their escape along the B direction) shifts the cyclotron frequency and introduces two additional motional modes (magnetron rotation and trapping oscillation).³⁷ A host of ion trap configurations²⁷ and operating modes³⁸ has been devised to select individual or particular combinations of these ion motional frequencies. For example, it is possible to trap positive and negative ions simultaneously^{39,40} and distinguish between them by circularly polarized quadrature excitation.⁴¹ Perhaps the most useful recent innovation is the use of resonant quadrupolar rf excitation, which (in the presence of the damping effect of ion–neutral molecule collisions) effectively ‘shrink-wraps’ ions into a small packet at the center of the trap,^{42,43} for order-of-magnitude improvements in signal-to-noise ratio and mass resolving power, as well as in the efficiency of ion remeasurement, MS/MS, and external ion injection.

Because the ICR relaxation time (analogous to T_2 in NMR) varies inversely with pressure, it is possible to obtain ultrahigh FT-ICR mass resolving power by acquiring an undamped time-domain transient ICR signal for several seconds or longer: for example, FT-ICR mass resolving power of $m/\Delta m \simeq 400\,000\,000$ at m/z 18 (H_2O^+)⁴⁴ and $m/\Delta m \simeq 2\,000\,000$ for ubiquitin ions of mass 8565 Da⁴⁵ have been reported. Even higher precision is possible for closely-spaced mass doublets, as in a recent FT-ICR determination of the mass of $^{20}\text{Ne}^+$ at ppb accuracy.⁴⁶

Finally, although the room-temperature detection limit for broadband FT-ICR/MS is about 150 ions,⁴⁷ it is possible to detect a *single* multiply-charged ion (e.g. a DNA molecule of 100 000 000 Da). Alternatively, Penning trap techniques based on SQUID detection at 4.2 K can detect an individual singly-charged ion.⁴⁸

The present summary is intended to provide a brief overview of ion cyclotron resonance development to its current state. More than 160 FT-ICR systems have been installed worldwide, and the number is increasing rapidly with recent demonstrations of detection and sequencing of DNA and proteins of 30 000 Da and higher.⁴⁹ For further details and examples, the

reader is referred to other reviews on the early development of continuous wave magnetic field-scanned instruments,^{50–52} early development of FT-ICR,⁵³ and numerous recent summaries of the vast potential of FT-ICR/MS for analytical, biological, and chemical applications.^{27,54–68}

Alan G. Marshall. b 1944. B.A., 1965, Chemistry, Northwestern University, Ph.D., 1970, Physical Chemistry, Stanford University (with John Baldeschwieler). Successively instructor II, asst. professor and assoc. professor, University of British Columbia, Vancouver, B.C., Canada, 1969–80; Professor of Chemistry and Biochemistry and Director, Campus Chemical Instrument Center, Ohio State University, 1980–93; Professor of Chemistry at Florida State University and Director of ICR Program at National High Magnetic Field Laboratory, Tallahassee, FL, 1993 to present. Approx. 200 publications. Prior research areas: nuclear magnetic relaxation and NMR determination of RNA secondary structure. Current research specialty: Fourier transform ion cyclotron resonance mass spectrometry.

Martin, Gérard J. Maryvonne L.: Ode to Ethanol

Gérard J. Martin & Maryvonne L. Martin

Université de Nantes-CNRS, Nantes, France

Probably because of its social connotations, ethyl alcohol has always been a favorite analytical probe of research workers. In its earliest days, NMR rapidly succumbed to its charm. Did it not inspire Arnold in 1951 to record the first proton spectrum of an organic species¹ (Figure 1)? This particular molecule has always held a privileged place in France, and not least amongst French physicists. Convinced of the importance of tracking down the specific properties of the ethanol molecule, one of us entered the world of research by exploring the potential of NMR spectroscopy to study hydrogen bonding in water/alcohol mixtures. One of the first ¹H NMR spectrometers to be acquired in France in 1957 therefore consumed quite a considerable amount of ethanol. The nominal frequency of this primitive spectrometer (Trüb-Taüber, Zürich) was 25 MHz, and in order to observe a spectrum the 0.6 T magnetic field was swept through the resonances in the absence of a locking device. The whole spectrometer system, which would have needed at least a 30 m² room, was installed in a dark cupboard in Prof. R. Freymann's laboratory—under the stairs of the venerable Sorbonne! The operator had a narrow gap, 1-m wide, in which to rush backwards and forwards between the various knobs of the machine, chasing the magnetic field which had an irrepressible tendency to escape from its resonance conditions. Here, there was neither the need nor room for a chair!

Unfortunately, in spite of the efforts of the most brilliant NMR specialists, we had to wait nearly 20 years before it was technically possible to run our first ²H NMR spectrum of alcohols. The frequency stability of our electromagnet spectrometer, a WH-90 Bruker equipped with an external locking device, was only of a few hertz per hour but, despite this, natural abundance deuterium was accessible in Nantes (a region known for its Muscadet wine).

It was whilst investigating chemical mechanisms that we noticed a rather intriguing behavior pattern of the relative intensities of the methyl and methylene ²H NMR signals. These were measured on ethyl acetate obtained from ethyl bromide samples and differed according to whether the latter had been purchased from Prolabo or from Aldrich. Taking into account the sensitivity and resolution available at that time, we put this 'supplier' effect down to impurities and electronic deficiencies. This proves that, despite having an ethyl group in common with ethanol, these chemicals do not have its power to inspire further investigation. It was nearly two years later that our interest in ²H NMR was revived, following an advertisement published in the daily press by the French Treasury Department. This dealt with the highly sensitive problem of wine chaptalization and offered a prize of 1 million FF to the person(s) who could, by analyzing the finished wine, detect whether sugar had been added to the grape must before fermentation. Unauthorized chaptalization

Figure 1 After more than 40 years the three lines of ethanol observed by Arnold¹ in ¹H NMR at 32.4 MHz (a) have lost nothing of their enticement. Now observed in natural abundance ²H NMR at 61.4 MHz (b, c,) they have even gained in elegance. They show that pure ethanol is not identical according to whether it is obtained from wine (c) or from beet sugar fermentation (b). Consequently ethanol from chaptalized wine will differ from ethanol formed purely from grape sugars. Therefore (c) is an NMR quality label of the Bordeaux wine under investigation. Since only 50 to 300 mL of wine are necessary for the NMR experiment, interesting sensory parameters can also be determined on the same bottle!

is a serious financial problem, not only for France but for the European Union as a whole, contributing rather too efficiently to the overproduction of wine. In 1980, 7×10^9 L of wine were produced in France from about 11×10^9 m² of vineyards. The lowest quality or table wines, most of which were bought by the state for distillation on the basis of their alcoholic grade, made up more than 65% of the overall production. The finest quality wines, VQPRD, on the other hand, represented only 22%. Unofficial estimates showed that more than 10^5 tons per year of sucrose were being illegally used for wine enrichment. Fermenting this sucrose mountain would produce a 'wine' lake of 0.5×10^9 L in France alone. With the help of the rest of Europe's sucrose, a sizeable increase in this lake's volume would certainly be obtained.

Most previous studies on chaptalization had concentrated on the detection of minor components normally absent from wine and whose presence could be attributed to added sucrose. However these strategies failed with the progress in sugar-refining methods. Since, from the chemist's point of view, wine can be reduced, somewhat irreverently, to mainly water and ethanol, we decided to investigate ethanol with the following questions in mind: is deuterium statistically distributed on the different molecular sites and, if not, does the natural deuterium distribution depend on the botanical origin of the sugar precursor? This was the beginning of an exciting research project. NMR revealed that Nature is in fact a fascinating laboratory where isotopomeric molecules are biosynthesized in perfectly reproducible conditions for a given botanical species grown in a given environment. If the deuterium content in the methyl position of ethanol is arbitrarily given the statistical value 3, the methylene site is characterized by a factor which not only deviates strongly from the statistical value of 2, but also differs significantly for ethanol derived from grape (≈ 2.55) and beet (≈ 2.75) for instance (Figure 1). A method based on the NMR investigation of 'labeling without enrichment' was born.² To keep up with fashionable practice in an evocative spirit (wines have 'spirits'* don't they?), we chose the acronym SNIF-NMR for 'Site-specific Natural Isotope Fractionation studied by NMR' (and left it up to those less serious to add the second 'F' for factors).

With technical improvements in the performances of the commercial NMR spectrometers, in the theoretical algorithms for quantitative determination, and in the statistical procedures of data analysis, precisions of up to 0.2% in the isotopomeric contents of ethanol (for instance!) are now accessible. Possibly combined with isotope ratio mass spectrometry, SNIF-NMR transforms natural or synthetic end-products into rich sources of information on their disappeared precursors and on the whole history of their elaboration.³ It renders possible the determination in a one-pot experiment of all primary and secondary kinetic isotope effects involved in a given chemical reaction. It also provides simultaneous determination of all primary and secondary thermodynamic isotope effects in chemical equilibria and gives access, in the same experiment, to the liquid-vapor fractionation factors of different isotopomers. It enables chemical or biochemical mechanisms to be inferred from the isotopic distribution measured on the products alone and information can even be obtained on the stereospecificity of reaction steps which introduce methylenic hydrogens in the course of biosyntheses in natural media.

Although a wide variety of molecules is accessible to SNIF-NMR, fermentation ethanol is certainly the most universal probe for tracing back the fate of any kind of carbohydrate and therefore for inferring the botanical, geographical, and

temporal origin of plant products.³ The consumption of ethanol by NMR has increased enormously in the last few years since the different official laboratories of the EU are now equipped to characterize several thousands of wines every year. The possibility of setting up a business offshoot of this research field was explored by the CNRS, and Eurofins S.A., created in 1987 in Nantes, was the first company to carry out and develop the SNIF-NMR concept. All the analytical steps involved in an authentication diagnosis of various food products, beverages, aromas, etc. are now fully automatized and computer-controlled. A data bank of several thousand authentic samples has been built up.

Ethanol still occupies a distinguished place in our NMR work and, even after all these years, not only have we not been discouraged by the monotony of its three ^2H lines but we are still amazed by the wealth of information contained in such a simple spectrum—on the physiological behavior of a plant precursor, on the weather which prevailed during the photosynthesis and the elaboration of fruits, and on the 'treatment' by man of authentic natural products.

NOTE

* Spirits: volatile compounds easily obtained by distillation.

McConnell, Harden M.: Spin Chemistry

Harden M. McConnell

Stanford University, Stanford, CA, USA

My graduate research at the California Institute of Technology during 1947–50 under the supervision of Norman Davidson would be described as ‘physical inorganic chemistry’ today. Then and now, one cannot carry out chemical research without developing an interest in atomic and molecular electronic structure. As a graduate student I developed a special curiosity about the quantum mechanics of electron spin as it relates to electronic structure. For example, I was impressed by Slater’s rules for multiplet splittings in atomic spectra and included some of my own ‘back-of-the-envelope’ calculations on multiplet splittings in diatomic hydrides in an addendum to my Ph.D. thesis. Even today, almost 50 years later, I clearly remember a lecture by Linus Pauling on electron spin correlations in the valence state of carbon in methane. As a National Research Fellow in the laboratory of Robert Mulliken, I worked on charge-transfer molecular complexes, but remained titillated by problems involving spin. For example, while at the University of Chicago I wrote a short letter to the *Journal of Chemical Physics* dealing with the catalysis of *cis/trans* isomerization of ethylene by paramagnetic substances, again involving a problem in molecular spin quantum mechanics.

On leaving Chicago in 1950 to take a position as a research chemist at Shell Development Company in Emeryville, California, my fascination with theories of molecular electronic structure had become tempered by the realization that (in 1950) it was virtually impossible to calculate anything of chemical interest theoretically with even semiquantitative accuracy. Thus, there was no way to test the then current and sometimes competing theories of molecular electronic structure, such as valence bond theory or molecular orbital theory. Fortunately, this depressing situation was about to undergo a dramatic change, through the developments of electron and nuclear magnetic resonance spectroscopy.

The first NMR spectrum that I ever saw was that of $\text{CF}_2=\text{CH}_2$, brought to me as a paradoxical problem by Charles Reilly, also a research chemist at Shell. For one who was interested in spin problems, the analysis of this spectrum was ‘a piece of cake’. It was also straightforward to extend this analysis to molecules with other point group symmetries.¹ But my principal interest in this spectrum came from the fact that the various molecular spin–spin coupling constants depended on electron spin correlations within the molecule, a subject I explored theoretically in a rather large number of publications.^{2–4} A major subsequent development was the discovery by C. A. Hutchinson, Jr. and S. I. Weissman that (electron spin)–(proton spin) hyperfine coupling constants in organic free radicals in solution could be observed in electron spin magnetic resonance spectroscopy. These free radicals, as well as organic free radicals in crystals, provided a direct, powerful means to determine electron spin distributions in molecules, and to test theories of molecular electronic structure.⁵ There are now numerous publications

describing such comparisons. One pleasant surprise in these comparisons was the finding that the molecular orbital theory of alternate π -electron hydrocarbons developed by H. C. Longuet-Higgins provided an excellent first approximation to the spin distributions in these molecules, and that valence bond theory led to negative spin densities on certain carbon atoms as observed experimentally.^{6,7} From the point of view of determining spin distributions in molecules, there is no fundamental difference between electron and nuclear magnetic resonance. Hyperfine splittings, and thus spin distributions, can be determined from splittings in electron magnetic resonance spectra, as well as from paramagnetic shifts in nuclear magnetic resonance spectra.^{6–8}

The above interplay of problems involving electron and nuclear spin systems has continued in my laboratory even when problems of molecular electronic structure were not involved. Examples include measurements of the rates of electron-transfer reactions,^{9–11} molecular diffusion in biological membranes,^{12,13} and studies of the structures and compositions of antibody combining sites.^{14–17}

Today, in 1994, high-speed computers have brought about a true revolution in the techniques available for determining molecular electronic structure, as well as for developing and applying sophisticated magnetic resonance techniques. In this era of big computers, big machines, and big budgets, I have found it expedient to retreat into more primitive areas of science.

In retrospect, I cannot judge what impact these magnetic resonance studies during the period 1950–65 had on the chemists’ view of molecules, but they certainly removed the anguish I felt in 1950 concerning molecular electronic structure theory.

McDowell, Charles A.: Four Decades of Chemical NMR at the University of British Columbia (UBC)

Charles A. McDowell

University of British Columbia, Vancouver, British Columbia, Canada

Nuclear magnetic resonance studies in the Department of Chemistry began in the mid-1950s with the construction of a broadline NMR spectrometer. The apparatus used phase sensitive detection and was built round a 6 in. Varian model V-4007 magnet. B. A. Dunell and his graduate student R. Grant, used it to study motion in stearic acid and some of its salts. The department acquired its first commercial spectrometer in 1956, a Varian high-resolution 40 MHz machine. Later I persuaded our Dean to provide funds to convert it into a dual-purpose Varian V4200/4300B spectrometer, probably the first such facility in Canada. A homemade variable temperature probe assembly provided a versatile spectrometer which was much used by faculty and graduate students, for liquid- and solid state NMR studies. The spectrometer was upgraded to perform at 60 MHz in 1961. The first solid state studies using the 40 MHz dual-purpose spectrometer were carried out by D. F. R. Gilson, a graduate student, now at McGill, and myself in 1957–58 on hydrocarbon/urea and thiourea inclusion compounds.¹ Using deuterio-urea and deuterio-thiourea as host matrices to reduce the proton–dipolar interactions between guest and host, it was clearly demonstrated for the first time by NMR that the guest molecules rotated about their long axes, or executed other motional behavior in urea inclusion or supramolecular compounds. These conclusions were confirmed later by others and particularly by deuterium spin echo studies. The early studies also included investigations of molecular motion of several enclathrated molecules and charge-transfer complexes.

L. W. Reeves, who had an extensive background in NMR having done postdoctoral work with W. G. Schneider at the National Research Council, Ottawa, and R. E. Connick at Berkeley joined the department in 1958. Reeves quickly started a research program on relaxation processes and chemical-exchange phenomena. Soon, with students and a postdoctoral fellow, E. J. Wells who had done his Ph.D. studies at Oxford with R. F. Richards, he built a spin echo apparatus, the first pulse spectrometer in the department. This equipment was used for extensive studies on spin–lattice effects and two- and multiple-site chemical-exchange reactions. Later Reeves and his group, including P. Englefeld, E. Krawkower, and K. Shaw, because of the need for sophisticated digital data collection, built a more elaborate pulse spectrometer around a Varian 12 in. magnet.

The 1960s saw the addition of many faculty members with research interests in preparative chemistry. Amongst those was L. D. Hall, a carbohydrate chemist who had been a postdoctoral fellow with F. A. L. Anet, then at the University of Ottawa. Hall made extensive use of CW and methods like INDOR. In addition, later, after the arrival of the Bruker

BKR-322 S spectrometer, his group used pulsed proton NMR in his structural studies on carbohydrates. In the late 1960s there were added Varian A-60 and HA-100 spectrometers, a JEOL C-60 with a JLA-5 computer, a Varian T-60, and in 1972 a Varian XL-100 high-resolution FT instrument. In 1974 we acquired a Varian CFT-20 machine for proton and ¹³C determinations.

The group of faculty members interested in solid state and condensed matter NMR studies was augmented by the appointment of E. E. Burnell in 1968. He had completed his Ph.D. studies under A. D. Buckingham, and gained postdoctoral experience with M. Bloom at UBC and in Basel with P. Diehl. That same year C. A. Fyfe joined me as a postdoctoral fellow and began his introduction to solid state NMR studying molecular motion. Because of the continuing need for more facilities, particularly for the study of solid state and condensed matter phenomena, the department obtained a Bruker BKR-322 S pulsed spectrometer. Elliott Burnell, B. A. Dunell, I, and our students continued to use this instrument for about 15 years. Of course, it was upgraded from time to time. Later when employed for deuterium-echo studies, an Oxford superconducting magnet was added. The spectrometer was later interfaced to an Intel 8080 microprocessor and a Nicolet 1280 computer. E. Burnell and his students made many significant studies of membranes and liquid crystals with this equipment. B. A. Dunell and his students, particularly, J. A. Ripmesster, and a postdoctoral fellow C. A. Ratcliff, both now at the National Research Council, Ottawa, studied molecular motion in solids. It was also extensively used by my students P. Raghunathan, A. W. Khanazada, and D. S. Williams, in addition to the existing Varian dual-purpose spectrometer, to study molecular motion of organic compounds as guests in deuterio-clathrate hydrates and charge-transfer complexes. Dr. P. S. Allen, a visitor from the laboratory of E. R. Andrew (Nottingham), and now at the Faculty of Medicine (Edmonton), contributed notably to these studies. This group also carried out an extensive study of the temperature dependence of spin–lattice relaxation processes in those systems.

Spin–rotational relaxation measurements at various temperatures from 80–400 K were made by R. Ikeda, a postdoctoral fellow from Nagoya, and myself on polycrystalline NH₄ClO₄ which showed that above 200 K spin–rotational interactions were predominant in proton spin–lattice relaxation. To extend the studies to 4.2 K, a new spectrometer was built incorporating a modified Robinson oscillator operating at low rf powers to observe wideline proton spectra at these low temperatures. Weak signals were enhanced by accumulating spectra with a Varian C-1024 time-averaging computer. It was shown that the anomalous lineshapes observed occurred because of the quantum-mechanical tunneling rotations of the NH₄⁺ ions. Later studies by Z. T. Lalowicz, a postdoctoral fellow from Poland, P. Raghunathan, and myself showed composite motions occurred involving coupling of the rotor states with lattice phonons.

Early in the 1970s, A. G. Marshall, who had completed his Ph.D. with J. D. Baldeschweiler at Stanford, joined us. Soon he and M. B. Comisarow invented and built the first Fourier transform ion cyclotron mass spectrometer. Particularly with his student L. G. Werbelow, Marshall also established a noteworthy research program in liquid state NMR. By this time there was very active research in practically

all aspects of chemical NMR. There was a great need for higher resolution spectra, so in about 1975 it was decided to build a high-field spectrometer. Using funds mainly from UBC sources, a 270 MHz superconducting magnet was bought from Oxford Instruments. We were fortunate to obtain an obsolete Bruker/Nicolet pulse FT spectrometer console which our electronic workshops most skilfully upgraded to perform at 270 MHz. L. D. Hall was notably involved in the evolution of this machine, which was probably the first high-resolution NMR superconducting magnet spectrometer built in Canada. It was soon heavily used for high-resolution spectra for the preparative chemists on the faculty, but mostly by L. D. Hall and his students who, later, with G. A. Morris, a postdoctoral fellow who had completed his Ph.D. with R. Freeman at Oxford, carried out some of the early applications of 2D NMR studies on carbohydrates. Subsequently, Hall used this equipment in his initial foray into chemical aspects of NMR imaging.

Though, as early as 1968, attempts had been made to obtain grants from NRC to purchase a Varian 220 MHz spectrometer, it was not until 1976 that I was successful in obtaining the long-sought financial support from NRC. Augmenting this grant with funds from UBC sources, by 1978 we had obtained a Bruker WH-400 high-resolution spectrometer and a WP-80 machine for routine studies. Also a Bruker CXP-200 solid state spectrometer for solid state and condensed matter NMR studies was delivered in 1979. The Bruker CXP-200 spectrometer proved versatile and has continued to be used about 24 h daily. Several additional probes were constructed including specially designed ones equipped with a goniometer for single-crystal NMR studies, and a specially designed variable temperature probe for studies on solids with quadrupolar nuclei.

The CPX-200 spectrometer was used later mainly by my group starting with A. Naito, K. Akasaka, a visitor from Kyoto, and S. Ganapathy, who first studied the ^{13}C – ^{14}N dipolar–quadrupolar interactions in the NMR spectra of single crystals of l-alanine.² They gave a quantum mechanical interpretation of the experimental observations which proved to be seminal. This work was soon followed by CP MAS studies and equally successful theoretical interpretations, spectral simulations, and evaluations of the magnitudes and orientations of the spin parameters of several amino acids and related compounds. Extensive studies in collaboration with R. Barker, K. Takegoshi and D. L. Sastry of single crystal NMR, including 2D exchange spectra, yielded accurate values for the principal values and their orientations of chemical shift tensors and quadrupole coupling tensors in a host of amino acids and other organic compounds.³ Studies of the orientational dependencies of spin–lattice relaxation and spin diffusion were also carried out.

By 1986, C. A. Fyfe returned to join the faculty. He brought with him a Bruker CXP-100 and an MSL 400 spectrometer, together with a Doty microscopic NMR imaging probe. He quickly reestablished his very active research program studying

the CP MAS spectra mainly of zeolites and polymers. About that same time the department was able to obtain an NSERC grant to purchase a Bruker MSL-200 console which was combined with a 200 MHz superconducting magnet already available. The addition of Doty MAS and DAS probes gave us greater access to much needed additional solid state NMR facilities. Making good use of these new opportunities, my group, which over time included A. Root, A. Kubo, R. Challoner, and T. Nakai, expanded the range of our activities to include MAS studies of spin diffusion processes⁴ and spin–lattice relaxation processes and thus rediscover Andrew's rotational resonance, spin–spin interactions in two-spin systems, and two-dimensional exchange phenomena. We also investigated many new multiple pulse sequences. In addition the group contributed many theoretical innovations including novel applications of Floquet theory to interpret the NMR manifestations of rotating solids.⁵

The department in the late 1980s added several faculty members with research interests in biological aspects of chemistry and there was a demand for higher field spectrometers. Thus were added Varian XL-300, Bruker AM-300, AC-200, AMX-500 and most recently a Varian UNITY-500, high-resolution spectrometers. We probably now have the greatest concentration of NMR spectrometers with superconducting magnets of any chemistry department in Canada.

McLauchlan, Keith A.: NMR Memories

Keith A. McLauchlan

University of Oxford, Oxford, UK

At the National Physical Laboratory in 1960, Ray Freeman, Ray Abraham, and I shared the first high-resolution 60 MHz spectrometer in Europe, under the direction of John Pople and David Whiffen. It was continuous wave, and field homogeneity ('shim') coils and field/frequency locking were still to be invented. A flux-sensing device ('superstabilizer') provided reasonable stability, but to obtain sufficient resolution was tedious.

Each morning the magnet was 'cycled', by increasing the field to a higher value than the resonance one for a time before reducing it. Hysteresis then produced, one hoped, a 'flat' field profile. Its effectiveness depended on the procedure used, and it was a continuous source of friction that we used different techniques, thereby 'ruining' the field for the next user. After cycling came the systematic tracking of the probe about the center of the magnet on a grid pattern, until a 'good spot' was discovered, detected by the observation of extensive 'ringing' in the rapidly-scanned spectrum of acetaldehyde. This procedure often took several hours, and the good spot usually appeared late in the evening.

This changed with the invention of shim coils by Golay, which also broke the domination of Varian patents in NMR, being introduced by Perkin-Elmer. We were obsessed by the mathematics of their orthogonality, but found them easy to use once we stopped trying to *calculate* which should be changed.

David Whiffen returned from a visit to Zürich where he had been shown the world's first field/frequency locked spectrometer in the laboratory of Hans Primas, who was also behind the development of a very remarkable commercial spectrometer (Trüb-Taüber) which employed three locked frequency sources. It was years ahead of its time, sold mainly in eastern Europe, and became very familiar to all of us who traveled there and found ourselves trying to fix it. Within half a day of Ray Freeman hearing of his achievement, he had locked our own spectrometer, using an audiofrequency sideband technique, and making the lock-in detectors himself. This opened new opportunities, and we moved immediately to field and frequency-swept double resonance studies, first homonuclear and then heteronuclear. We had so many different frequencies applied to the system that beats proliferated, and you really had to understand what you were doing to get anywhere. Ray left for a year at Varian, whence the first commercial field/frequency locked spectrometer, the A-60, soon resulted. It provided the major advance of precalibrated charts, all spectra having been previously calibrated by the generation of audiofrequency sidebands. Ray returned, and we performed a triple resonance experiment together which required very high resolution (he recognized and exploited the slow sweep condition) and immense stability. We ran the same spectrum without any adjustments to the spectrometer for hours on end, waiting until all the oscillators used happened to be at the right frequencies at the same time; this caused Varian some difficulties from others who expected their spectrometers

always to be as stable. A little later the HA-100 appeared, providing field/frequency locking to an internal sample; its principle was not widely understood, and for years I was telephoned by service engineers from all over Europe to diagnose faults.

Our work was centered largely on the measurement of the relative signs of coupling constants, needed to determine which possible analysis of a spectrum was the correct one. It relied upon the ensemble nature of NMR spectroscopy, which allowed experiments to be performed inside subensembles in the sample. This was always a sticking point in lecturing on the subject. These experiments represented the leading edge of research and thanks to Ray produced the first trivial term in NMR, 'spin tickling'.

Another method then arose for getting the new information: multiple quantum spectroscopy. As the radiofrequency power of the spectrometer was increased the NMR signal was known to broaden and saturate. I realized that the observed pattern actually contained sharp transitions, which were completely reproducible, and David Whiffen told me what they were. Although M. Bloom and J. N. Shoolery had reported a double quantum transition before, this was their first use in analysis, and was the forerunner of multiple quantum coherence experiments.

We then turned to the absolute signs of coupling constants, which were believed to be impossible to measure since the spectrum was invariant to a complete sign change. David Buckingham suggested a new principle: we should make the nuclear dipolar interaction nonzero in a way which told us its sign and see whether the observed splitting in the spectrum, now given by the sum of the dipolar and scalar couplings, increased or decreased from its value in isotropic solution. This was the first experiment on partially-oriented molecules. Initially we oriented polar molecules inside a strong electric field inside the spectrometer, and suffered many explosions; the experiment was performed much more carefully by A. D. McLean later, but the same result was obtained. We also played with orientation by crystal lattices, in clathrates and zeolites, and in stretched polymer films. But then A. Saupe and G. Englert published the first spectra in liquid crystalline solvents, and it became obvious where the future lay.

In 1965 I left for Oxford, and it seemed to me that the interesting phase of NMR was over. I still believed it when after giving a lecture in Pittsburgh an unknown young man in the audience stood to ask a question. It was my first meeting with Richard Ernst, who may just have been right in thinking the whole field still had more of interest in it than I did.

Soon after, Rex Richards and I combined with Oxford Instruments to design the first genuinely high-resolution superconducting magnet with top sample loading, which was married to Bruker electronics to produce a 270 MHz spectrometer. It was designed specifically for biochemical studies. Another era of applications of NMR had begun, but apart from a brief flirtation with chemically induced dynamic nuclear polarization, this was my last contribution to NMR.

(RYDMR), effects of magnetic fields in chemistry, biochemistry and biology, including human health.

Mehring, Michael: Advent and Evolution of High-Resolution NMR in Solids: A Personal View

Michael Mehring

Universität Stuttgart, Stuttgart, Germany

In standard spectroscopy the intensity of a signal (absorption, transmission, number of particles, etc.) is measured for different frequencies (wavelength, wavenumber, etc.) using a frequency selective (dispersive) device. In fact, standard NMR spectroscopy proceeded for quite some time along the same lines where the magnetic field was swept. A qualitatively different approach to spectroscopy was introduced by the spin echo of Erwin Hahn and co-workers.¹ It demonstrated for the first time that spin interactions could be ‘manipulated’ by radiofrequency (rf) pulses. A wealth of multiple pulse experiments and finally high-resolution solid state techniques evolved from this.

Another important ‘manipulation’ of spin interactions was achieved by ‘magic angle spinning’ (MAS) introduced by Andrew² and Lowe³ and co-workers. This technique achieved high-resolution right away by ‘averaging’ all second-rank tensor interactions which otherwise give rise to line broadenings. If all second-rank tensors can be averaged to zero by MAS, what about doing the same in spin space? Exactly this was achieved by the Lee–Goldburg⁴ experiment where a strong rf field was applied at the magic angle in the rotating frame. This did not lead to very high resolution in solids however, although it achieved a lengthened decay which corresponded to a narrowed NMR line.

Later John Waugh and co-workers⁵ designed a four-pulse sequence based on ‘average Hamiltonian’ theory⁶ which was also capable of reducing higher-order correction terms, resulting in true highly resolved NMR spectra in solids.^{7,8} I am very grateful for having been present in the Waugh group at that time and taking part in those fascinating experiments. There was a very particular atmosphere in the Waugh lab where I was together with David Ellett, Mike Gibby, Bob Griffin, Alex Pines, and Won-Ku Rhim. Average Hamiltonian theory⁶ had paved the way for an easy proposal of new pulse sequences and for performing exciting experiments like the ‘magic sandwich’.⁹ The atmosphere was highly creative with John Waugh guiding every co-worker individually, either by an approving smile or a smart remark. It was the same time when Alex Pines proposed together with Mike Gibby and John Waugh an experiment based on the permutation of his name which turned out to be very useful in the end.¹⁰ It is this experiment, namely ‘proton-enhanced nuclear induction spectroscopy’ which is still mostly used today when high resolution in solids is required. Soon after, monographs appeared which reviewed and summarized these techniques.^{11,12}

It became evident at the beginning that one major benefit of high-resolution techniques applied to solids was the observation of shift anisotropies which are otherwise masked

Figure 1 Room-temperature ^{13}C NMR magic angle spinning spectra ($\omega_{\text{rot}}/2\pi = 45\text{ MHz}$) of solid fluoranthene (middle) and of the one-dimensional conductor (fluoranthenyl) $_2\text{SbF}_6$ (bottom). The spectrum of fluoranthene in liquid solution (top) is included for comparison.^{18a} (Reproduced by permission of the American Physical Society)

by dipolar interactions.⁸ Starting with ^{19}F nuclei,^{8,13} these were soon followed by ^{13}C nuclei,^{10,14} and finally high-resolution spectra of protons were observed.^{15,16} My personal interest was always in applying these novel techniques to solving special solid state physics problems. I therefore found it very fascinating to resolve very small Knight shifts in ordinary metals¹⁷ and organic conductors.^{18,19} An example of the first ^{13}C and ^1H Knight shifts in organic conductors is shown in Figures 1 and 2.

The basic experiments discussed here were later extended into two-dimensional versions²⁰ and were combined with magic angle spinning and specially designed multiple pulse sequences. Major extensions to these ‘classical’ high-resolution techniques were introduced by Alex Pines and his co-workers in the area of multiple quantum²¹ and double rotation NMR.²² Bob Griffin and co-workers²³ applied high-resolution techniques to biological materials and developed MAS methods in order to measure distances between nuclear spins, based on the dipole–dipole interaction, very precisely. Using simpler techniques, Nino Yannoni and co-workers²⁴ also used this interaction in order to determine ^{13}C – ^{13}C nuclear distances in basic materials like polyacetylene and C_{60} .

I have not tried to review the field but rather give a personal view on how I saw the subject developing.

Of particular interest are organic conductors and superconductors, conducting polymers, electron-transfer processes, and molecular electronics.

Mildvan, Albert S.: Early Applications to Enzymes of Paramagnetic Effects on Nuclear Relaxation

Albert S. Mildvan

Johns Hopkins University, Baltimore, MD, USA

Although my training was medical, I became committed to basic biochemical research early, inspired by excellent teachers of chemistry in high school, as an undergraduate at the University of Pennsylvania (Penn), and as a medical student at Johns Hopkins where, in 1953, ours was one of the first classes to hear lectures in biochemistry by the new Chairman, Albert L. Lehninger. My summers were spent in research in enzymology, the most exciting field in biochemistry, in the laboratories of Britton Chance at Penn and Albert Lehninger at Hopkins. In the 1950s one could easily monitor the velocity of enzyme-catalyzed reactions. However, the intermediate enzyme-substrate complexes were elusive. Inspiring work by Chance, combining rapid mixing with spectrophotometry had detected enzyme-substrate intermediates with peroxidase and catalase, and had elucidated all of the rate constants for their formation and disappearance.¹ However, nothing was known of the atomic structures of enzyme-substrate complexes or of the chemical basis for their unusual reactivity, resulting in overall enzymatic rate accelerations of chemical reactions by factors ranging from 10^6 - to 10^{16} -fold.

After completing a medical internship, I returned to enzyme chemistry via postdoctoral training. Coincidentally, in 1960 while I was a postdoctoral fellow in Cambridge, UK with G. D. Greville, the first high-resolution X-ray structures of the proteins metmyoglobin and methemoglobin were being solved by Kendrew and Perutz at the nearby MRC Unit.^{2,3} Although not enzymes, these structures demonstrated the power of a method which resolved individual atoms of a molecule. At that time I had also read several papers by Mildred Cohn who, in pioneering studies, had begun to apply NMR methods to enzymes, substrates, and their complexes. As Cohn pointed out, NMR, like X-ray, was a method with atomic resolution, with the advantage of being in solution. Using a Varian 60 MHz NMR spectrometer she reported in 1960 the first phosphorus spectrum of 0.5 M ATP showing separate, well-resolved resonances of the α , β , and γ phosphorus atoms.⁴ By selective changes in chemical shifts induced by protonation or by Mg^{2+} coordination, and by paramagnetic broadening with transition metal ions,⁵ she could tell which of the three phosphoryl groups of ATP were complexed. The sensitivity of NMR was still too low to study enzyme-bound ATP. However, Cohn was able to study enzyme- Mn^{2+} -substrate complexes indirectly by monitoring changes in the paramagnetic effects of bound Mn^{2+} on the longitudinal relaxation rate ($1/T_1$) of water protons.⁶ Eisinger, Shulman, and Blumberg had shown earlier that complexation by DNA enhanced the paramagnetic effects of Mn^{2+} on $1/T_1$ of water protons due to an increase in the correlation time for dipolar interaction between Mn^{2+} and its residual water ligands.⁷

Using this approach, Cohn and Jack Leigh obtained evidence for a substrate-bridge complex ($E-ADP-Mn^{2+}$) with the enzyme creatine kinase since enhanced water proton relaxation required all three components to be present. With enolase, a metal-bridge complex ($E-Mn^{2+}-2$ -phosphoglycerate) was suggested since the enzyme and Mn^{2+} alone gave enhanced water proton relaxation, and this enhancement decreased on subsequent substrate binding, probably due to replacement of water ligands on Mn^{2+} by the substrate.⁶ Based on this exciting work, I wrote to Mildred Cohn at the University of Pennsylvania and was fortunate in 1962 to obtain a postdoctoral position in her group.

As used by Cohn, the enhancement of $1/T_1$ by enzyme-bound Mn^{2+} was a qualitative method. Hence, my first project in her laboratory was to make the method quantitative, so that it might be used to measure dissociation constants, binding stoichiometries, and ultimately to count the number of residual water ligands on Mn^{2+} in binary and ternary complexes with enzymes and substrates. Because bovine serum albumin was stable, readily available in pure form, and was known from the literature to bind Mn^{2+} tightly, I started with this protein, titrating it with Mn^{2+} , and measuring $1/T_1$ of water protons on Jack Leigh's homebuilt pulsed NMR spectrometer which incidentally shared a magnet with an elderly Varian V4280A EPR spectrometer. As a check value, at each point in the titration, I used the EPR spectrometer to measure the free Mn^{2+} concentration. Gratifyingly, the binding stoichiometries and dissociation constants of Mn^{2+} -serum albumin obtained by both the enhancement of $1/T_1$ and independently by EPR agreed, establishing the $1/T_1$ method as a quantitative tool.⁸ In addition, a new parameter ϵ_b , the enhancement factor due to bound Mn^{2+} was defined and directly evaluated which was 11.5-fold for the one tightly bound Mn^{2+} on serum albumin. This parameter, which reflected both the residual number of water ligands on Mn^{2+} and the correlation time, changed dramatically in response to changes in pH, and with the addition of denaturants. However, serum albumin was not an enzyme and did not form ternary complexes. Hence, I enthusiastically began a study of pyruvate kinase, a glycolytic enzyme which required a divalent cation and catalyzed the reversible enolization and phosphorylation of pyruvate by ATP to form phosphoenolpyruvate and ADP. I purified the enzyme from rabbit muscle using a procedure worked out by Tietz and Ochoa⁹ and titrated the enzyme with Mn^{2+} . Like bovine serum albumin, and enolase, and unlike creatine kinase, pyruvate kinase bound Mn^{2+} tightly in the absence of substrates to form a binary complex with an unprecedentedly high enhancement factor (ϵ_b) of 30-fold.¹⁰ Next, titration of the pyruvate kinase- Mn^{2+} complex with the substrate phosphoenolpyruvate resulted in a marked decrease in enhancement, with a clear endpoint at an enhancement factor of 2.2, suggesting the formation of a ternary enzyme- Mn^{2+} -phosphoenolpyruvate bridge complex. The other substrates, pyruvate, ATP, and ADP also decreased the enhancement but to a lesser degree.¹¹

Importantly, the dissociation constants of Mn^{2+} and of each substrate from their enzyme complexes, determined by titrations measuring $1/T_1$, agreed with their respective K_M values, determined by the methods of enzyme kinetics, thus establishing active-site binding for Mn^{2+} and for each substrate. The $1/T_1$ data thus established the random order binding of substrates to the enzyme- Mn^{2+} complex and suggested the

formation of an enzyme- Mn^{2+} -phosphoenolpyruvate bridge complex. However, substrate coordination by the enzyme-bound Mn^{2+} was not directly proven since we had looked only at water protons rather than at the substrate itself. In 1966, a direct look at the paramagnetic effects of pyruvate kinase-bound Mn^{2+} on $1/T_1$ of phosphoenolpyruvate by continuous wave NMR was not easy. While continuous wave proton NMR was sensitive enough, the vinyl protons of this substrate would probably be too far from the bound Mn^{2+} to establish the structure of the ternary complex, and continuous wave ^{31}P NMR and ^{13}C NMR were certainly not sensitive enough. However, Tietz and Ochoa had shown that, in a side-reaction, pyruvate kinase also catalyzed the phosphorylation of the fluoride ion (F^-) by ATP to yield fluorophosphate (FPO_3^{2-}) and ADP.⁹ Since fluoride was a substrate analogous to pyruvate, and fluorophosphate was analogous to phosphoenolpyruvate, a realistic experiment presented itself, namely to determine by ^{19}F NMR the effects of pyruvate kinase- Mn^{2+} on $1/T_1$ of fluoride and of fluorophosphate.¹²

Accordingly, I first carried out kinetic and binding studies with F^- and FPO_3^{2-} by $1/T_1$ measurements of water to facilitate the design of the ^{19}F NMR experiments. In the ^{19}F NMR experiments, carried out on a Varian HA-60 spectrometer, T_2 was measured by linewidth and the product $T_1 \times T_2$ was measured by rf power saturation, a method long forgotten in NMR but still occasionally used in EPR spectroscopy. In control experiments, the paramagnetic effects of Mn^{2+} on $1/T_1$ and $1/T_2$ of F^- and FPO_3^{2-} were measured. Using the $1/T_1$ values, Jack Leigh and I independently calculated Mn^{2+} to fluorine distances in the binary Mn^{2+} - F^- and Mn^{2+} - O_3PF complexes, using the dipolar term of the Solomon-Bloembergen equation, and obtained values of 2.1 Å and 4.4 Å, respectively. The agreement of these distances with those obtained from X-ray crystallographic data in the literature was so good that I repeatedly rechecked the units in our calculations to make certain that they were indeed Å rather than meters. We thereby became convinced that $1/T_1$ was indeed a powerful structural tool.¹²

With pyruvate kinase, our results were also clear cut. While Mn^{2+} alone profoundly increased $1/T_1$ and $1/T_2$ of F^- , the presence of pyruvate kinase deenhanced these effects by competing for the Mn^{2+} , thus arguing against an enzyme- Mn^{2+} - F^- bridge complex. On the other hand, pyruvate kinase significantly enhanced the effects of Mn^{2+} on the ^{19}F relaxation rates of FPO_3^{2-} qualitatively demonstrating an enzyme- Mn^{2+} - O_3PF bridge complex. A similar Mn^{2+} to fluorine distance on the enzyme as off was calculated, thus defining the structure of the complex as pyruvate kinase- Mn^{2+} - O_3PF .¹² The $1/T_2$ value of enzyme-bound FPO_3^{2-} was exchange-limited, yielding the rate constant for the dissociation of FPO_3^{2-} from the E- Mn^{2+} - FPO_3^{2-} complex. Since this rate was 10^3 -fold faster than catalysis, we were indeed observing a kinetically competent complex. Thus NMR was not only a structural tool but also a kinetic tool, hence ideal for enzyme studies.

Eleven years later, after the introduction of higher magnetic fields and Fourier transform methods, the structure of the pyruvate kinase- Mn^{2+} - O_3PF complex was confirmed by ^{31}P -relaxation rate measurements by Thomas Nowak,¹³ a former postdoctoral fellow in my laboratory, and an enzyme- Mn^{2+} -phosphoenolpyruvate bridge complex was

detected by X-ray diffraction.¹⁴ As an independent investigator, I extended these methods to many other enzymes. In addition to substrate bridge (E-S-M) and metal-bridge (E-M-S) complexes, enzyme-bridge (M-E-S) and second-sphere complexes [E-M(H_2O)S] were detected.^{15,16}

Until 1969 paramagnetic effects on T_1 were limited to metal-ion requiring enzymes, which constitute only about one-third of all known enzymes. In 1965, Harden McConnell introduced the use of stable, paramagnetic nitroxides or spin labels as covalent EPR probes of macromolecular motion.¹⁷ At that time it seemed obvious to me that with T_1 measurements, a spin-labeled substrate could be used like Mn^{2+} for binding studies to an enzyme and for the measurement of intersubstrate distances on an enzyme which had no metal requirements. In 1968, as a visiting lecturer at Purdue University, I met Henry Weiner who had synthesized tempo-ADP, a spin-labeled analog of NAD^+ and had shown it to be a competitive inhibitor of alcohol dehydrogenase with respect to NAD^+ . At my invitation, Weiner came to Philadelphia, and together we showed that when alcohol dehydrogenase bound tempo-ADP, it enhanced the paramagnetic effects of the spin label on $1/T_1$ of water protons by as much as 80-fold. The enhancement factor was decreased on the subsequent binding of the other substrate, ethanol, to the enzyme, indicating the formation of a ternary enzyme-tempo-ADP-ethanol complex, and suggesting proximity between the two substrates.¹⁸ By measuring the effects of the enzyme-bound nitroxide on $1/T_2$ of the protons of ethanol itself we were able to estimate the intersubstrate distance on this enzyme as ~ 4 Å,¹⁹ a proximity confirmed 13 years later by X-ray diffraction.²⁰ These relaxation techniques have since been extended to many enzymes which do not require metal ions.

Morris, Gareth A.: The Origins of DANTE

Gareth A. Morris

University of Manchester, Manchester, UK

My introduction to NMR research came as an undergraduate at Oxford, where chemistry students enjoy a fourth (Part II) year devoted to research, in the autumn of 1975. Having taken an interest in electronics and computers while at school, and having enjoyed being taught by Ray Freeman, I chose to join Ray's NMR group for my Part II. At that stage Geoffrey Bodenhausen was grappling with instrumental obstacles to the measurement of T_2 values, and David Turner was measuring T_1 values. Our only instrument was a Varian CFT-20, a carbon-13 FT spectrometer which was too unstable to be used for proton NMR. Its great virtue was a computer system which offered almost complete control over the spectrometer; new experiments could be tried out quickly and easily by modifying the software. This was something of an art, as modifications had to be made in 16-bit machine code, within the 6000 words of memory allocated to the control program.

Ray suggested some projects involving spin locking and transient nutations, both of which required a high pulse duty cycle, so I set out to build a new radiofrequency power amplifier. At the same time I was trying to get to grips with the basics of pulsed NMR. Having read about Fourier series while at school, I was keen to see how much of pulse FT NMR could be explained using Fourier transforms. Since the CFT-20 could only produce rectangular pulses, a logical place to start was to try to predict the behavior of a regular train of pulses. The Fourier transform of such a sequence is a series of equally spaced sinc functions, so this suggested the idea of using a train of pulses to achieve frequency selective excitation. When I discussed the idea with Ray he was a little sceptical, so the idea remained untried until events took over.

By the end of February 1976 I was becoming restive, as the Oxford Part II system requires students to submit a thesis at the beginning of June and I had very little material. A visitor to the laboratory, Aharon Loewenstein, offered cold comfort: 'Cheer up', he said, 'Nothing in NMR happens on a timescale of less than five years'. Finally at the end of February 1976 my rf amplifier was completed, so at 11 o'clock one night I ran the first tests. Unfortunately a capacitor in the final stage arced, leaving me with a dead amplifier and no thesis material. The next morning I came into the laboratory and decided that it was time to put the ideas about selective excitation to the test.

We already had a CFT-20 program suitable for generating trains of pulses (this was for an ill-starred experiment¹ involving the use of transient nutations to identify spins with $T_2 < T_1$), so it took only a short time to set up a simple test. At that time our favorite sample was ^{13}C -enriched methyl iodide, since this gave strong signals even at low field. The pulse sequence (later named DANTE) did indeed give frequency-selective excitation, exciting just one of the four lines of the proton-coupled methyl iodide quartet. By this stage Geoffrey Bodenhausen had arrived in the laboratory, and he suggested gating on the proton decoupler at the start of the free induction

decay, causing the excited signal to change frequency. This led naturally to the idea that by gating the decoupler on during excitation and off during data acquisition, the technique could be used to excite proton-coupled carbon-13 multiplets selectively, allowing overlapping spectra to be disentangled.

The application to 'real' molecules proved straightforward^{2,3} (although one of our chosen examples, menthone,³ proved to be a severe case of virtual coupling), and I was able to produce a satisfactory thesis from a few weeks' work. We subsequently⁴ went on to examine in detail the relationship between the linear response approximation and the Bloch picture, and demonstrated a number of other applications for pulsed selective excitation including selective spin locking, hole burning, and saturation transfer. By this time, however, most of our attention had shifted to a far more important topic, two-dimensional NMR. Surprisingly, DANTE is still in widespread use despite the advent of improved soft pulse instrumentation and techniques. Its prime advantages are its predictability and ease of use, and the fact that it produces selective excitation which is phase coherent with normal hard pulses. Recent uses in medical NMR, for example cardiac tagging, also exploit the characteristic multiple sidebands.

The most difficult part of the whole exercise was agreeing a suitably pithy name for the experiment. I had been reading the *Divine Comedy* (in translation, after a brief and unequal struggle with Dante's Italian) and had been struck by the parallel between the path taken by Dante and his guide Virgil through Purgatory and the trajectories of nuclear magnetizations during our experiments. Dante's Purgatory consists of a series of seven successive circular ledges running around a mountain, one for each of the seven deadly sins (arranged approximately in order of interest, with Pride at the bottom and Lust at the top). Souls progress heavenwards by circumnavigating each ledge before moving on to the next, just as our magnetizations alternately precessed during delays and were nutated by pulses. Ray was convinced by the analogy when he discovered diagrams in books on Dante that matched our simulated magnetization trajectories almost exactly, so we settled on the acronym DANTE (Delays Alternating with Nutations for Tailored Excitation) for our pulse sequence.

Nagayama, Kuniaki: The First Protein Two-Dimensional (2D) NMR

Kuniaki Nagayama

The University of Tokyo, Komaba, Tokyo, Japan

In the middle of April 1977, two professors had been awaiting my return from spring vacation. In the office of Kurt Wüthrich, my cheerfulness after a family tour to Müren rapidly diminished on hearing the determined voice of Ernst saying, 'Oxford may be very close to the development of 2D NMR for proteins. We must work rapidly not to be beaten by that group'. Until that time, I had been watching as an unconcerned spectator while the competition between the Zürich group directed by Richard Ernst and the Oxford group directed by Ray Freeman continued in the development of 2D NMR. Now, however, I really understood my own personal position in this situation. Wüthrich ordered me to complete the current work and to produce the world's first 2D NMR spectrum of a protein as soon as possible. His voice was stern and he would not accept refusal, and I realized then that I would be facing one of the hardest times ever in the coming few weeks.

Nonstop writing of 2D NMR software began immediately and the Nicolet 1180 minicomputer occupied exclusively by me became covered by the printouts dumped from the Teletype roller. The circumstances in 1977 for software development were poor compared with current conditions, but the computer system with its 12-in. disk cartridge (DIABLO) was rather modern for those days. I utilized any useful resources at hand, such as my 24-h (overnight work every other day) utility softwares from Nicolet and custom programs used for 1D NMR from Bruker. I tried to make a small program satisfying the minimum requirements for performing the desired 2D J spectroscopy of proteins. When I was almost buried in paper at the end of April, my software development was finished and I was left with five thousand lines of code written by ASSEMBLER. A pretest was then made to check my program with a mixed solution of five amino acids: alanine, isoleucine, histidine, methionine, and tyrosine. I then asked Gerhard Wagner to use his protein, BPTI (basic pancreatic trypsin inhibitor), as the first sample for the 2D NMR program. I had already understood that the quality of J spectroscopy was critical for the resolution and, therefore, required sharp resonances. The BPTI solution was then prepared in high concentration (10 mM), placed in the HXS-360 NMR (Bruker 360 MHz), which was equipped with a newly designed cavity probe to avoid the troublesome B_1 inhomogeneity, and measured at a high temperature (60°C). The J spectrum of BPTI clearly resolved the fine structures and exhibited very neat J coupling constants for all 20 methyls in the second dimension. It was May 5, 1977, two weeks after the start of my sleepless nights and five weeks after my attendance at the British Biophysical Society Meeting on NMR held at Oxford. There I had been a stranger just becoming acquainted with

Geoffrey Bodenhausen and David Turner who were working on 2D NMR in Oxford. The well-resolved 2D J spectrum of 20 methyls in BPTI was immediately reported to *FEBS Letters* and soon rejected due to the lack of any biological relevance. With our angry sentiments it was sent to *Biochem. Biophys. Res. Commun.* and promptly accepted in July.¹

At the end of November 1976, I had come to Zürich as the first postdoc invited by Wüthrich and Ernst to join in a research project emerging between the two professors that continued for 10 years thereafter. It was just one year after I had seen Wüthrich at the Taniguchi Symposium on Biophysics held in Kyoto. He told me that he remembered well my presentation on the helix-coil transition of polypeptides in the 6th International Biophysical Congress in Moscow in 1972 and offered me a position in the joint project. I became obsessed with the idea that I could study near the genius who had opened up the new NMR world by his FT revolution. So, with no hesitation, I decided to accept his offer even if I sacrificed my position as a research associate in the University of Tokyo. In May 1976, Wüthrich informed me that their research proposal had finally been formulated and asked me to study a 2D NMR paper² sent under a separate cover. My first reaction to the preprint full of density matrices and the new notion was a mixture of wonder and bewilderment. I convinced myself that there was something completely new there, but I could not understand what it was; then I simply reported to Wüthrich that I had tried to understand the paper as a simplification of NMR by taking an analogy with another paper³ sent in the same mail.

My success with the software development and the NMR experiment, where I was able to shorten the period of my task from two months to two weeks, was not only a credit to the encouragement of Ernst and Wüthrich but also due heavily to the proper software training by Peter Bachmann who had been employed by Ernst in the project. Bachmann gave me personal lessons in how to manage the programming with the machine language ASSEMBLER. All persons concerned and unconcerned had been quite fascinated by the beautifully stacked 2D NMR plot of BPTI¹ and firmly believed that we would see a prosperous future for 2D NMR and a new age in protein NMR. We then extended J spectroscopy to spin echo correlated spectroscopy (SECSY),⁴ which was used to take the first 2D correlation NMR of proteins. From the beginning of my encounter with FT NMR, the mathematical harmony behind it had been always my enchanting driving force and above all led me to the application of several mathematical tools, such as the cross-section projection theorem,⁵ delayed acquisition and the similarity theorem,⁶ and time reversal and frequency inversion.⁷ I had thought that the spin engineering required to develop pulse sequences useful in particular applications of 2D NMR was not my business but that of the Ernst group. Now, the main stream of 2D NMR and protein NMR is provided by the perfect combination of COSY and NOESY,⁸ and my work flashed over the J spectroscopy of proteins is destined to fade away into the shadows of history. On the other hand, the development of my 2D NMR software with a command interpreter and a disk system was more blessed. The program was extended twice and implemented on Aspect 2000 Bruker computers by Bachmann. It has also been extended to workstations where it can show the beauty of 2D or 3D NMR spectra with color graphics. When we see

modern NMR systems where 1 Mbyte of 2D data are Fourier-transformed within a few seconds, I always remember my time at Zürich where the *J* spectrum of BPTI with 1 million data points was obtained after an overnight run on a Nicolet 24 bit minicomputer.

Nakanishi, Koji: First Encounter with NOE in Natural Products—the Ginkgolides

Koji Nakanishi

Columbia University, New York City, NY, USA

I have been engaged in structural studies of natural products throughout my career, including our current interests in ligand/receptor interactions. The emphasis has been to apply and develop various spectroscopic methods for structural studies, our present efforts being centered on the exciton coupled CD method. The emphasis in developing spectroscopic methods has even led us to advance structures which we suspect may have to be revised later, simply because spectroscopic interpretations led to the suggested structure and we were unable to find any rationale to dispute the result.

My first encounter with NMR was around 1957 when working on the triterpenoid antibiotic pristimerin (**1**); several groups in the UK and India were also working on its structure because of its use in folk medicine (India and China) and bright orange–red color. In 1955–56 we reported¹ that the Kuhn–Roth oxidation method showed the presence of a minimum of three methyl groups; in pre-NMR days, the number of methyl groups used to be estimated from the number of moles of acetic acid produced by vigorous oxidation. Soon thereafter, the tiny narrow strip chart depicting the 30 MHz NMR of pristimerin measured at Varian showed seven methyl singlets, an enormous help in determining the final structure.²

A case demonstrating the immense power of NMR was encountered during studies of chromomycin A₃, an anticancer agent which was being used clinically. In the early 1960s, thanks to the generous support of Martin Packard and Jim Shoolery of Varian, the company supported two scientists to run the 100 MHz instrument at Tohoku University, where I was from 1963 to 1969. One of them, Norman Bhacca (now at Louisiana State University) performed one of the most exhaustive double and triple resonance experiments in those days on chromomyciquinone (**2**), a key compound in the structural studies of chromomycin A₃.³ Not only did NMR clarify the connectivities leading to structure (**2**), but to our surprise it also showed that (**2**) contained one unexpected extra carbon.

An exciting event was the ‘discovery’ of intramolecular NOE by Dr. Vyn Woods (a Varian postdoc, now deceased)

and Iwao Miura (he later moved to Columbia University and became a legendary NMR structural person in the Chemistry Department there; currently at Otsuka Pharmaceutical Co.). We were working on the structure of the ginkgolides, a group of diterpenes isolated from the ‘fossil tree’ *Ginkgo biloba*. We had 10–20 g of the various ginkgolides, GA (ginkgolide A), GB, GC, and GM, prepared about 50 derivatives, and encountered many interesting chemical reactions, rearrangements, and photochemistry during intensive structural studies. The group, led by Masao Maruyama (currently at Miyagi Kyoiku University) worked day and night for several years and had great fun. This was the last of the romantic and classical structural studies I did which involved many chemical degradations and derivatization reactions (Figure 1).⁴ As far as we know, they are still the only natural products containing a *t*-butyl group, the unusual biosynthesis of which was studied by callus incorporation experiments.⁵ Although no biological activity could be found for these aesthetically pleasing cage compounds with six five-membered rings including three γ -lactones, a spiro carbocycle, and a five-membered ether ring, subsequently the ginkgolides were found to be potent inhibitors of the platelet activating factor,⁶ with over-the-counter annual sales exceeding \$700 million.

The NMR of GA is too simple because the quaternary carbons and four lactones divide the protons into several groups with no connectivities [Figure 1(a)]. In order to gain more information, the lactones were reduced with lithium aluminum hydride (LAH). Upon accidental heating in an oven, the product octaol cyclized back to give the original pentacyclic cage(!), GA triether, the only difference being that now the three lactones had been replaced by ether rings. The triether exhibited a far more complex spectrum [Figure 1(c)] because of the proton connectivities arising from the new proton peaks designated cc', ee', and ff'. The similarity in the NMR of GA and GA triether-*d*₆, prepared by using LAD instead of LAH, shows that the original cage structure is retained in the triether [Figures 1(a) and (b)].⁴

During exhaustive decoupling experiments on the triether, Vyn and Iwao found that irradiation of the *t*-Bu peak led to 10%–33% enhancement in certain peak areas without an appreciable decrease in the halfbandwidth. Instead of dismissing this as an integrator error, they repeated the measurements and concluded that it was a new phenomenon. Vyn and Iwao suspected that it might be related to the Overhauser effect, where irradiation of unpaired electrons leads to enhancement of nearby proton signals,⁷ and interpreted their observation as being due to an intramolecular Overhauser effect (spring 1966); this greatly facilitated our ginkgolide structural investigations. Around this time the first paper on NOE dealing with β,β -dimethylacrylic acid and a cage compound by Anet and Bourn appeared in the literature.⁸ Vyn and Iwao's stubborn and uncompromising attitude had led to the finding of the NOE, unknown at that time in the natural products field. One of the first examples in our lab is shown in Figure 2. I presented a talk on NOE and the ginkgolide structure at the 4th IUPAC Symposium on Natural Products in Stockholm in June 1966,⁹ and the NMR paper was submitted in the fall¹⁰ together with four other communications leading to the final structure of the ginkgolides. We did not grasp the full implications of NOE when we first submitted our findings,¹⁰ and hence the title was simply ‘Some Aspects of their NMR Spectra’. However, its immense potential in structure determination

Figure 1 Proton NMR of ginkgolide A (GA) and derivatives at 100 MHz. (a) Bottom trace. GA in TFA. A, B, C, etc. denote the protons shown in the structure of GA. (b) Middle trace. 'GA triether'-d₆ obtained upon LAD reduction followed by pyrolysis, NMR in CDCl₃/D₂O. All lactonic carbonyls in GA are replaced by CD₂; differences in proton shifts between Figure 1(a) and (b) reflect difference in anisotropic effects. (c) Upper trace. 'GA triether' obtained upon LAH reduction followed by pyrolysis, NMR in CDCl₃/D₂O. All lactonic carbonyls in GA are replaced by CH₂, leading to a far more complex spectrum

Figure 2 Effect of irradiating the *t*-butyl group in GC tetraacetate in TFA at 100 MHz. Traces show superimposed spectra with and without irradiation. Proton H, which is remote from the *t*-butyl group, shows no change in peak shape, whereas the signals of protons I and J, which are close to the *t*-butyl group, both undergo a ca. 20% increase in integrated area; although an increase in peak heights is seen, no appreciable decrease occurs in the halfbandwidths ($W_{1/2}$). A 4% NOE was also observed with proton F (not shown)

was soon realized and the next paper was more appropriately titled 'The Nuclear Overhauser Effect, a Unique Method of Defining the Relative Stereochemistry and Conformation of Taxane Derivatives'.¹¹

Biographical Sketch

Koji Nakanishi. b 1925. B.S., 1947, Ph.D., 1954, Nagoya University. Assistant Professor, Dept. of Chemistry, Nagoya University 1955–58; Professor, Dept. of Chemistry, Tokyo Kyoiku University 1958–63; Professor, Dept. of Chemistry, Tohoku University 1963–69; Professor, Dept. of Chemistry, Columbia University, 1969–80; Centennial Professor, Dept. of Chemistry, Columbia University, 1980–present; Chairman, Dept. of Chemistry, Columbia University, 1987–90; Director of Research, The International Centre of Insect Physiology and Ecology in Kenya, 1969–77; Director, Suntory Institute for Bioorganic Research in Osaka, 1978–91. Approx. 600 publications. Research interests include isolation, structural and bioorganic studies of bioactive compounds, retinal proteins, interaction between ligands and neuroreceptors, structural studies of oligosaccharides, and application of various spectroscopic methods, especially circular dichroic spectroscopy.

Norberg, Richard E.: NMR in Urbana and St. Louis

Richard E. Norberg

Washington University, St. Louis, MO, USA

UNIVERSITY OF ILLINOIS

I entered the University of Illinois as a physics graduate student in the fall of 1946. After some service as a teaching assistant I received research assistant support through to my Ph.D. by working with Arnold Nordsieck in the construction and testing of his compact synchro-driven analog differential analyzer. In addition to being a gifted theorist, Nordsieck was a master machinist. In a 1948 colloquium lecture Nordsieck described the Stanford and Harvard bulk sample NMR experiments. I decided to follow Erwin Hahn (a year ahead of me) into NMR research and in the spring of 1949 I began to share a lab with Erwin under the eaves on the top floor of the physics building. We had the support of two splendid electronics technicians, Howard Knoebel and Lynton Kypta. Much of the equipment either was homemade or World War II surplus. In daily conversations and lectures Erwin led me as I worked through the Stanford and Harvard papers and then as he proceeded with his own famous work on spin echoes. James Bartlett, a theorist who had encouraged Hahn, agreed to serve as my nominal thesis advisor and to authorize the modest necessary expenditures from the ONR contract which supported much of the departmental research.

Charles Slichter arrived from Harvard to join the faculty at Illinois in the fall of 1949. He at once took an interest in my work and I became his first graduate student, although he was not yet officially able to direct graduate theses. Between Hahn and Slichter I had unique mentors in NMR. During a splendid fall 1949 solid state physics course taught by Fred Seitz, I first learned something about the hydrogen in palladium system and its systematic variation of bulk magnetic susceptibility as the hydrogen concentration is changed and the 3d band filled. This struck me as a potentially interesting solid system for NMR investigation and, with encouragement from Seitz, Nordsieck, and Slichter, I set to work on a steady-state proton NMR investigation of shifts and relaxation times in HPd. I chose to work with protons within the 30 MHz 1.5-mil rf skin depth of 30 mil Pd wire which I had loaded in an H₂ atmosphere following glow discharge surface preparation. The thesis experiments were a bit eerie since the Pd rf coil appeared to be empty. Some measurements used a short segment of H-loaded Pd wire as the terminating stub of a nearly quarter wavelength rigid coaxial line. When Erwin Hahn discovered spin echoes late in 1949, I quickly converted my apparatus to pulsed spin echo investigations of the HPd system. I reduced transient coil disease for the free-standing Pd rf coils by potting the coil assembly with molten sulfur. As I completed my January 1951 thesis, I discovered that Henry Torrey's group at Rutgers had also been using proton NMR to study HPd.

Figure 1 shows the pulsed NMR apparatus used for my HPd work¹ and (with the addition of a pulsed boxcar integrator)

Figure 1 Pulsed NMR equipment at Urbana, fall 1950

for subsequent alkali metal studies with Slichter² and with his student Don Holcomb.³ The dc field was provided by a D-shaped electromagnet constructed in 1938 for mass spectrographic work and powered by a Navy surplus selenium rectifier and parallel arrays of storage batteries. A frequency-modulated transitron oscillator NMR detector operating in a shimmed region of the pole face regulated the magnetic field. The panel at the lower left of Figure 1 shows the handle of a carbon pile resistor fine control on the magnet current. Above this are rack panels associated with the CW and pulsed rf crystal oscillators. In front on the table is the twin-T rf bridge with its dummy arm and the coax leading to the sample coil in the magnet. The signal from the bridge output went to a Wallman cascode preamplifier or to a surplus radar if strip and thence to a communications receiver with its if stages broadbanded to 30 kHz. The three oscilloscopes in the picture included one (bottom right) which could accept an external trigger and be conveniently used for pulsed NMR displays. The central rack panel controlled magnet regulation and a field modulation capability. On the right is a rack with a surplus frequency meter for field calibration and two communications receivers—one for detection of the transitron field control signal, and one for reception of the pulsed NMR free induction decays and spin echoes. Before we introduced the use of a boxcar integrator (a long time constant gated integrator and a dc amplifier), the data had to be recorded photographically from the oscilloscope and then measured mechanically. Warm-sample temperature control up to 75°C was achieved with a noninductively wound electrical heater inserted in a ceramic tube and placed within the Pd coil. Colder temperatures between 30°C and –60°C were achieved with a copper trough containing CS₂ or turpentine. Around the trough, copper tubing carried acetone from a reservoir containing a mixture of acetone and Dry Ice. The recycling pump and flow valve regulator consisted of a colleague and beaker. It all worked to within $\pm 1^\circ\text{C}$.

After my thesis defense in January 1951, I took the Nordsieck differential analyzer to the Radiation Laboratory at Berkeley for a LINAC design problem in W. Panofsky's group. After my return to Urbana in the spring of 1951, Slichter and I did spin echo studies of ²³Na motional narrowing in metallic sodium.² From mid-1951 to the summer of 1954 I had a University of Illinois appointment in physics and in

the Control Systems Laboratory (CSL), where I worked on computer–radar interface problems. During this time I worked on two novel pulsed nuclear resonance experiments. One was to continue work on alkali metals at night and on weekends with Slichter and with Don Holcomb. This work used our new pulsed boxcar integrator, which had been constructed to improve the limited signal-to-noise ratio which characterized the earlier HPd measurements. Since we were not yet using phase sensitive detection, it was necessary to calibrate the unipolar boxcar output for nonlinear diode detector response. The alkali metal work benefitted greatly from the help of Herb Gutowsky and Tom Carver.

A second new experiment arose from discussions about NQR with Charles Slichter and Myer Bloom. At CSL I had built another pulsed NMR rig to investigate the possible utility of digitally-encoded spin echoes and stimulated echoes for computer memory use. The computer memory idea did not work out, but I was able to use the 30 MHz pulse rig in a search for pulsed pure quadrupole echoes that had been predicted by Bloom. After some troubles with piezoelectric transients, I found the NQR echoes in NaClO_3 powder and then in a single crystal. After a few weeks the pulse rig was trucked over to the physics building and NQR was up and running there within a few hours. In another of those early coincidental efforts, it turned out that Erwin Hahn, then at the IBM Watson Lab, was not only working on an attempted spin echo computer memory but had also discovered pulsed NQR, so we published^{4,5} adjoining NQR papers.

WASHINGTON UNIVERSITY

In August 1954 I came to Washington University as a visiting faculty member to replace George Pake, who was on leave at Stanford. Things worked out well and I remained at Washington University. From Pake and from Don Maxwell I inherited a small group with AFOSR support and graduate students C. Robert Bruce, James Burgess, and Irving Lowe. I was already familiar with the George Pake/Sam Weissman magnetic resonance groups since the Illinois and St. Louis groups quite regularly exchanged visits to each other's laboratories.

At Washington University I found faculty research collaborators in George Pake, Jack Townsend, Sam Weissman (in chemistry), and Barry Commoner (in botany). Eugene Feenberg and Henry Primakoff were the leading Physics Department theorists and they both maintained an interest in the NMR work. In St. Louis, as in Urbana, most of the magnetic resonance equipment was homemade. The single pulsed NMR apparatus had been assembled by Maxwell and Lowe. There were several modest electromagnets and permanent magnets. The latter included one permanent magnet whose field had been homogenized for high-resolution work by the heroic efforts of Bob Bruce. He used a micromanipulator and CW proton NMR from a small mineral oil sample to map contours of constant field in various gap planes. Then he shimmed the field by using the field plot templates and emery cloth to remove iron plated onto two brass discs to be mounted on the magnet pole faces. After homogenization, the magnet provided a resolution of about one part in 10^7 for a static proton liquid sample of 12 μl . Thermal stabilization of the magnet

was required since the 27 MHz proton resonance frequency changed by 6 kHz per $^\circ\text{C}$.

In a 1955 collaboration with Sam Weissman,⁶ Bruce used his homogeneous magnet and high-resolution proton NMR to make the first NMR measurement of an electron exchange rate too slow to study with ESR. In 1956 Bruce, George Pake, and I pointed out⁷ that radiation damping could significantly affect CW high-resolution NMR spectra. Bruce had observed radiation damping in his thesis work. Although the topic was discussed by others, it remained somewhat obscure until the growth of commercial high-resolution NMR.

Beginning from studies of ^1H and ^{19}F NMR in polymers, Irving Lowe and I became interested in the lineshapes of simple dipolar-coupled rigid lattice arrays of nuclear spins $\frac{1}{2}$. Lowe discovered that the free induction decays in cold polyethylene and Teflon were nonmonotonic but rather showed a distinct beat structure. Lowe set out to undertake single crystal studies and CaF_2 was an obvious choice because of its 100% abundant simple cubic array of ^{19}F spins and negligible abundance of ^{43}Ca . In addition, George Pake⁸ and Bob Bruce⁹ had studied the angular variation of the ^{19}F CW absorption line in CaF_2 and found good agreement with the second moment calculations of Van Vleck.¹⁰ It was obvious that the Lowe beats reflected a lineshape somewhat more rectangular than a Gaussian and so we set to work to examine the Fourier transform relation between the free induction decay and the steady-state lineshape. Another connection with Illinois occurred when Bruce used the Nordsieck differential analyzer at Urbana to integrate his first derivative CW lineshapes and obtain the absorption lines published⁹ and compared (via our Fourier transform theorem¹¹) with Lowe's free induction decays. I believe that Lowe's subsequent work on the ^{19}F line in CaF_2 has made it by far the best-determined lineshape in any spectroscopy. Leonard Bowen, our early colleague in some of the polymer work, was a postdoctoral associate who returned to Australia and set up the first pulsed NMR apparatus on that continent.

Working with Irving Lowe was a delightful experience. Each day we would discuss some spin quantum mechanics and then early the next morning Lowe would arrive at my office to see if I had discovered the errors in the previous day's efforts. George Pake recommended me for an Alfred P. Sloan Fellowship and the award of that money allowed Lowe to stay on as a postdoc following his fall 1956 degree. During that time Lowe invented magic angle spinning¹² as a method for the pulsed NMR of rigid lattice solids. In another of the many coincidences in NMR, Raymond Andrew independently was developing MAS in CW experiments. My new students William Yen and Horst Kessemeier analyzed the first MAS results on CaF_2 and Teflon. The published transform spectra¹² were the results of tedious transformations using a mechanical desk calculator. Kessemeier went on to do the first FT examination of MAS-resolved chemically shifted lines in a solid spectrum.¹³ Mg_3P_2 , Zn_3P_2 , and AIP were chosen for their large internuclear separations and consequent narrow rigid lattice lines. Arden Sher saw our first ^{129}Xe signals and Mario Engelsberg did a beautiful study¹⁴ of the interference of pseudodipolar and dipolar interactions for ^{31}P in InP. Yen did the first pulsed NMR studies of self-diffusion in a rare gas solid (^{129}Xe in solid xenon).¹⁵ Yen's ^{129}Xe work led to a series of rare gas measurements¹⁶ on ^{131}Xe (William Warren, Don Cowgill, and Harry Ringermacher);

^{21}Ne (Rodney Henry and Bruce Sirovich); and ^{83}Kr (Don Cowgill, Eric Madaras, Jose Vithayathil, and Matt Commens). Warren's ^{131}Xe work led to the observation of a resolved composite solid echo–quadrupole echo in solid xenon. The ^{83}Kr work, in particular, led to a continuing collaboration with Peter Fedders, in which appreciation of the effects of intraspin cross relaxation¹⁷ was crucial to understanding the NMR results. In solid neon and krypton, the rotating frame $T_{1\rho}$ methods of Slichter and Ailion¹⁸ and of Look and Lowe¹⁹ were essential for precise determinations of diffusion parameters and of spectral diffusion rates.

K. Luszczynski arrived in St. Louis from Great Britain in 1959 and we set out to do low-temperature pulsed NMR of quantum fluids. With James Opfer, James Gaines, and David Biegelsen we investigated spin–lattice relaxation, diffusion, spin diffusion, and magnetic susceptibility of ^3He in gas and liquid in ^3He – He(II) solutions.

In the summer of 1969, I met a St. Louis area high school student named Mark Conradi. He entered Washington University as a freshman in 1970 and at once began to work as an NMR electronics technician and laboratory wizard. Mark stayed on for his graduate work and later returned as a tremendous addition to our faculty. Conradi's Ph.D. thesis work²⁰ on dilute *ortho*- H_2 (*o*- H_2) in rare gas solids and liquids opened a research avenue which has continued to this day via the work of Carl Edwards, Gregory Mohr, Joseph Ganem, Jonghun Lyou, and Zhen Yan. Here again collaboration with Peter Fedders has been essential. The Raman-driven quadrupolar phonon transitions among the $J = 1$ *o*- H_2 molecular m_J states relax the protons and give rise to the characteristic power law temperature variations of T_1 . This signature permitted us to recognize²¹ the presence of molecular hydrogen in hydrogenated amorphous silicon. A decade of work followed on host-bonded hydrogen, H_2 , HD, and D_2 in amorphous semiconducting films, where collaborations with James Boyce (Xerox PARC) and William Paul (Harvard) have been very fruitful. Dan Leopold made the first of our deuteron magnetic resonance structural measurements in amorphous semiconductors. He has been followed by Vincent Bork, Martin Volz, Plinio Santos, Yong Wah Kim, Robert Corey, Jeffrey Bodart, Pei Hsuon Chan, and Mary Jane Kernan.

The semiconductor work also led to the discovery of deuteron multiple echoes²² for HD and *o*- D_2 physisorbed and trapped on internal surfaces in semiconductors and on MgO and BN.²³ The multiple echoes provide unique signatures for the first physisorbed layer and for HD/ H_2 and *o*- D_2 /HD isotopic separation. Other collaborations with Conradi have produced such results as the successful application of NMR to high-pressure studies in a diamond anvil cell²⁴ and current work on metal hydrogen systems with David Baker, Robert Bowman, Richard Barnes, and David Torgeson. This has

extended earlier metal hydride work by Nouha Salibi, Bico Ting, Harry Ringermacher, Vincent Bork, and Martin Volz.

Over the many years, I have been particularly fortunate in the many excellent colleagues with whom I have worked.

Oldfield, Eric: NMR Adventures in Chemistry and Biology

Eric Oldfield

University of Illinois at Urbana-Champaign, Urbana, IL, USA

After undergraduate research on gibberellin glycosides (with Jake MacMillian) and on lipid bilayer structure (with Geoffrey Eglinton) at Bristol, I moved to Sheffield to work with Dennis Chapman on the development of new methods to study membranes. We began with an analysis of wide-line pulsed NMR,¹ but it soon became clear that ¹H NMR methods were going to be difficult in that one had to settle either for low resolution (on multilayers, or intact membranes), or high resolution on less-than-intact systems. We also disliked the spin-label method, since knowing where the label was or how it might distort its local environment always seemed problematic. Fortunately, we had on hand some chain deuterated lipid (which had been made by Unilever to aid in their ¹H wide-line assignments), Bill Derbyshire at Nottingham had a wide-line deuterium probe (for studying ²H₂O in meat), and I had an idea.

We obtained the first ²H NMR spectra of membranes in early 1971, and were pleased to see that gel and liquid crystalline spectra were very different and that cholesterol caused large spectral changes—an increase in quadrupole splitting from ~27 kHz to 50 kHz above the pure lipid-phase transition temperature and an essentially identical spectrum below T_c ²—indicating that the ²H NMR method was going to be a useful new, nonperturbing probe of lipid and membrane structure. We then biosynthetically incorporated ²H labeled fatty acids into real cell membranes, from *Acholeplasma laidlawii* B, and found surprisingly large amounts of gel phase lipid at the growth temperature.³ The ²H NMR method was then further developed by many groups, and at present appears to be one of the best spectroscopic techniques with which to study the structure of lipids and membranes. At Sheffield, we also began (in 1971) an exploration of ¹H magic angle sample-spinning of membranes with D. Doskočilová and B. Schneider in Czechoslovakia⁴—but it took about another 10 years for the technology to catch up with our needs, and in the 1980s we reported the first truly high-resolution (500 MHz) ¹H MAS spectra of lipids,⁵ work which was successful because of the special ‘inhomogeneous’ nature of the dipolar interactions involved.⁵ A natural outgrowth of this work was to investigate further the ¹³C lipid and membrane systems we had struggled with in the early 1970s,^{6,7}—such as lecithin–cholesterol and myelin^{8,9}—which now give spectacular resolution.

After graduate school, I moved in 1972 ‘temporarily’ to the United States to work with Adam Allerhand. Adam had the best (‘homebuilt’) ¹³C NMR spectrometer available, and we all badly wanted to see individual ¹³C sites in proteins—a feat accomplished with the 20-mm probe.¹⁰ We used to cram 2–3 g of protein into the tube, and wait—but the spectra were extremely nice¹¹—although generally restricted to nonprotonated carbons.¹² Of course, these days such amounts of protein seem absurd—although with labeling the numbers of ¹³C spins are about the same!

The results obtained in 1972–74 clearly showed the excellent spectral resolution of ¹³C NMR, where chemical shift nonequivalencies due to folding of >6 ppm were seen. These chemical shifts remained mysterious for about 20 years, even though without them modern higher dimensional studies of protein structure would be impossible. So after several attempts at explaining ¹³C shifts empirically, we eventually tried the quantum chemistry approach.¹³ It worked.¹⁴ Thus, if a good starting structure is available, it is now possible to predict ¹³C, ¹⁵N, and even ¹⁹F chemical shifts in proteins, an observation which should have significance for future use in structure prediction and structure refinement—both in solution and also in the solid state.

After several years at Illinois working on topics such as lipid–protein interaction (‘boundary lipid’) via ²H NMR,^{15,16} on analyzing phospholipid and glycolipid structure via ²H NMR,¹⁷ as well as developing the sideways-spinning probe for sensitivity enhancement,¹⁸ we moved our interests into the area of inorganic chemistry and the materials sciences. In particular, we began to investigate the much neglected nonintegral spin quadrupolar nuclei.¹⁹ Although MAS NMR of such systems had been reported much earlier by Andrew, the higher field strengths of the 1980s reduced second-order broadening such that very many nuclei (not just ¹³³Cs or cubic solids) became accessible. Also, we found that line narrowing of the central ($\frac{1}{2}$, $-\frac{1}{2}$) transition was much more effective at angles other than the magic angle, and variable-angle sample spinning began.^{20,21} However, MAS NMR was the preferred modality, and we began a decade-long exploration of (primarily) ¹⁷O NMR in inorganic solids, ranging from zeolite catalysts²² to mineral phases,²³ and using static samples from heme-proteins²⁴ to high-temperature superconductors.^{25,26} For the high- T_c materials, we used the method of magnetic ordering previously used in our ²H NMR studies of heme proteins,²⁷ and obtained exceptionally highly resolved spectra—19 out of 20 peaks resolved in YBa₂Cu₃O_{7-x}.²⁵

Our studies of quadrupolar nuclei eventually led to investigations of spin–spin relaxation, which we found was usually dominated by homonuclear and heteronuclear dipolar interactions.²⁸ This recently led to a useful technique for ‘editing’ out industrial catalyst binder (e.g. γ -Al₂O₃) resonances, which normally swamp the minor (but active) zeolite signals. We also recently introduced new methods using weak or selective pulse excitation, which enables quadrupole–quadrupole nucleus cross polarization, as well as the *quantitative* analysis of quadrupolar nuclei in solids, using weak-pulse spin echo excitation methods.²⁹

When taken together, these developments, as well as those of Lippmaa, Fyfe, Thomas, and others have opened up the whole world of inorganic chemistry and materials science to investigation by means of solid state NMR. However, it is remarkable how little *analysis* of the plethora of chemical shift and quadrupole coupling constant data has actually been performed—a situation remarkably akin to the protein chemical shift problem noted above. Thus, there is now no shortage of data,^{30,31} and it can be anticipated that new analyses of shielding and field gradient results will go hand-in-hand with price/performance improvements in computational hardware, over the next few years.

This leads to my final comment related to the general problem we have been posed by the editors: how did NMR develop? I think that it is fairly clear that not unlike the

Industrial Revolution, pure science drives technology and we all benefit from the technological developments. The discovery of NMR utilized World War II rf and magnet technology. Signal averaging and FT NMR used new computers, just as now we use the newest computers to perform dynamics trajectories or shielding calculations. The trick, of course, is to apply the new technologies in interesting new ways. Here, we often have to acknowledge the role of serendipity. This would probably be unsurprising to, for example, the discoverer of penicillin or lysozyme, or the first observers of spin echoes in liquids or multiple echoes in solids, but is perhaps not fully appreciated by new researchers. The '99% perspiration, 1% inspiration' axiom is probably about right.

Opella, Stanley J.: NMR Spectroscopy and Structural Biology

Stanley J. Opella

University of Pennsylvania, Philadelphia, PA, USA

PERSONAL PERSPECTIVE

It is an extraordinary privilege to be Professor of Chemistry at a major research university in the United States of America. The freedom to choose research goals and the responsibility to utilize public support wisely and creatively in pursuit of these goals, while training students in the ways of science, make this a unique and rewarding endeavor. The overall goals of my research program, which is in the Department of Chemistry at the University of Pennsylvania, are to develop NMR methods and instrumentation for the study of proteins and to apply NMR spectroscopy to determine the structures and describe the dynamics of proteins, especially those that are difficult or impossible to characterize by conventional approaches to structural biology. In practice, these research goals typically evolve into finding ways to master the correlation time problem, which results from large proteins and proteins in complexes reorienting so slowly that their resonances are too broad and weak for high-resolution studies.

From the day I first learned that structural biology existed, I have felt that it was the most important thing to understand and I wanted to be part of it. Structural biology is emerging as a comprehensive scientific method for describing, predicting, and altering biological organisms, including humans. It is truly contemporary science, based on the intellectual and technical revolutions that occurred in the fields of biophysics, molecular biology, and computation during the last decade. And it is one of the reasons that the 1990s are a wonderful time to participate in scientific research. For the first time it will be possible to understand how the macroscopic characteristics of life, such as reproduction and thought, are determined by the arrangements of atoms in polypeptides. I find it difficult to understand why so many students find fields firmly rooted in the past, such as literature, law, or finance, so attractive when contemporary chemistry and biology beckon.

Devastating hereditary diseases, such as sickle cell anemia or cystic fibrosis, provide dramatic illustrations of how enormous changes in biological function result from substituting a few atoms out of the several thousand in an individual protein. In contrast, much larger changes are tolerated without apparent consequences in some other proteins. This selectivity, which can only be understood through structural studies of proteins, provides opportunities for biomedical intervention in diseases as well as for the biotechnology industry to alter biological functions in ways thought to guarantee profits.

Of course, when I first heard of structural biology as an undergraduate chemistry major at the University of Kentucky, it was called bioorganic or biophysical chemistry. My understanding was that when the most powerful chemical

and physical methods were used to study proteins and other biopolymers, their structural and functional properties could be analyzed in atomic detail. I was fully convinced as a junior in college that by utilizing the most sophisticated instruments and methods of spectroscopy, it would be possible to understand biological phenomena at the same level of detail as chemistry and physics. I knew I wanted to do NMR spectroscopy as soon as I learned that it enabled biopolymers to be probed with sophisticated instruments and techniques in the laboratory of Stanford L. Smith at the University of Kentucky during an undergraduate research project. At that time I learned a lot about research from many informal discussions in the department, especially with Joseph Wilson.

I was fortunate to be a graduate student at Stanford in the early 1970s when the Chemistry Department was at the forefront of interdisciplinary studies. This enabled me to obtain a Ph.D. in physical chemistry under the aegis of Harden McConnell while working on solution NMR studies of proteins in the laboratory of Oleg Jardetzky. I learned valuable lessons from these two pioneers of biological magnetic resonance, who differ so much in style. At that time NMR studies of proteins were severely limited by the technical capabilities of commercial NMR spectrometers, especially their low magnetic fields. I performed my graduate research on one of the first continuous wave spectrometers converted to pulsed Fourier transform operation by Transform Technology, Inc. This enabled me to convert from the era of continuous wave to that of pulsed spectroscopy just as it moved from development to application laboratories, and I benefited tremendously in this from having the opportunity to work closely with Roy Johnson as the instrumentation and software were developed. My initial approach to overcoming the limitations of ^1H NMR studies of proteins in solution was to observe other nuclei, especially with ^{13}C and labeled-site ^{19}F NMR experiments.¹ Later on ^{14}N and ^{15}N were to become favorite nuclei for interrogation.²⁻⁴

As I was completing my graduate research at Stanford, I started to focus on what kind of research and training to pursue next. The day-to-day limitations of NMR spectroscopy of proteins were so severe that the outstanding goal was simply to get past the barriers of the technique so that you could start thinking about proteins. Even then, prior to the development of convenient cloning and expression systems, new proteins were being isolated regularly, but it was numbing for every discussion about a protein to start with its molecular weight and solubility rather than its function. In order to reconcile my belief that NMR spectroscopy was the best way to study proteins with its inability to work effectively with most proteins, I was determined to attack its limitations head on. Solid state NMR spectroscopy appeared to offer this opportunity, since here the methods were actually improved by immobilization of the sample rather than made worse as is the case for solution NMR spectroscopy. The attractiveness of this approach was apparent in the dramatic results emerging from John Waugh's laboratory at MIT, and it was a great opportunity for me to work in his laboratory as a postdoctoral fellow in 1975 and 1976. I read the initial papers on high-resolution solid state NMR spectroscopy very carefully, and came to the conclusion that this type of spectroscopy was going to revolutionize the way proteins were studied. After all, the first paper on proton-enhanced nuclear induction spectroscopy did say 'Studies of chemical shift anisotropy of rare species

(e.g. metals bound to *proteins*) or the dipolar structure of rare spin groups ... could be of value in structural studies'.⁵

As I began to write postdoctoral fellowship applications, I tried to systematize my ideas for protein NMR spectroscopy. I wanted to choose a protein system based on its biological importance, yet it still had to be tractable for spectroscopic experiments that were at an early stage in their development. The main issue certainly was size, but there are really two parts to this; the mass of the actual species in the sample tube since that determines the effective correlation time, and the complexity of the polypeptide chain that determines the number of resonances to resolve. The ideal system to start with for solid state NMR spectroscopy would have a large overall size due to many identical subunits that are symmetrically arranged. This would result in the situation where only a single polypeptide chain had to be studied, once the spectroscopic methods dealt with the correlation time problem. It would also have to be bacterial so that it could be both made in large amounts and labeled with stable isotopes.

I quickly decided on studying the coat proteins of bacteriophages. I first looked into the possibilities for the coat proteins of icosahedral viruses, but could find none with suitably short polypeptides. And then I learned about the filamentous bacteriophages because I was doing a lot of reading in the biochemistry library at Stanford and right at that time there was considerable activity in that department studying M13, a prototypical filamentous phage. I recall assuring several funding agencies that I could describe the coat protein in the virus particles in some detail during the two-year period of a postdoctoral fellowship. Of course, here it is 20 years later and I am still working on the problem. Considerable progress has been made in the last few years in describing the structure⁶ and dynamics⁷ of the coat proteins in the bacteriophage.

I joined the Department of Chemistry at the University of Pennsylvania as an assistant professor in 1976. At that time the department was still in the early stages of what was to become a spectacular development program initiated by David White, the Chairman who recruited and nurtured many of us. The greatest benefit of working in this department is the opportunity to work with the many talented and highly motivated undergraduate, graduate, and postdoctoral students who are here.

RESEARCH PERSPECTIVE

NMR Spectroscopy of Proteins

Even the earliest applications of NMR spectroscopy to proteins sought to identify spectral parameters that could be associated with the three-dimensional folding of proteins, primarily through the influence of the local protein environment on the chemical shifts of ^1H resonances. The first published NMR spectrum⁸ of a protein is presented in Figure 1(b). It is my favorite because it provides optimism. By recognizing that this spectrum could be turned into the multidimensional masterpieces of today with every ^1H , ^{13}C , and ^{15}N resonance resolved and assigned, it is possible to be hopeful about almost any spectrum that might be acquired. For example, the spectrum in Figure 1(a) is a conventional one-dimensional ^1H NMR spectrum of fd bacteriophage.⁹ Even though the predominant

Figure 1 A comparison of high resolution ^1H NMR spectra of two proteins: (a) fd coat protein in virus particles in solution in a high-field spectrometer;⁹ (b) ribonuclease in solution in a low-field spectrometer.⁸ The spectra were scanned from the original articles and their width and alignment adjusted in a computer. Hence the scale is appropriate only for qualitative comparisons.

species is a 50-residue coat protein, the lines are very broad and weak, remarkably similar to those in the spectrum in Figure 1(b). This comparison illustrates one of the primary objects of my research, and that is to develop instrumentation and methods so that a spectrum like that in Figure 1(a) can be the starting point for detailed structural studies. The spectrum in Figure 1(a) was obtained under conditions that yield quite high-resolution spectra for the types of samples that were used to obtain the spectrum in Figure 1(b); since the breadth of its resonances reflects the slow reorientation of the protein complex, it is an entirely different task to turn this spectrum into something usable.

Rapid isotropic reorientation of proteins in solution is essential for the use of instrumentation, methods, and interpretations based on isotropic chemical shifts, spin-spin couplings, and through-space dipole-dipole interactions that result in nuclear spin relaxation, and when that is missing spectra such as that in Figure 1(a) result. In some cases, specific, selective, and uniform labeling with ^{15}N and/or ^{13}C aid in the resolution and assignment of complex spectra. These, and other labeling strategies, especially with ^2H , extend solution NMR methods to somewhat more slowly reorienting proteins. However, none of these methods are usable with proteins that are immobilized by virtue of their being part of supramolecular structures in solution, such as virus particles, membrane bilayers, or in the crystalline or amorphous solid state. This is the domain of solid state NMR spectroscopy, even if the samples are actually solutions.

THE DEVELOPMENT OF SOLID STATE NMR SPECTROSCOPY OF PROTEINS

The most important reason for developing solid state NMR spectroscopy as a general method for determining the structures of proteins is that it will extend the range of proteins that can be described at atomic resolution to include membrane proteins. Both X-ray crystallography and multidimensional solution NMR spectroscopy are highly effective methods for determining the structures of proteins. However, they are restricted for practical reasons to a single class of proteins—water-soluble, globular proteins with well-defined tertiary structures that tend to crystallize but not aggregate—and only a minority of biological properties are expressed by the globular proteins of the cytoplasm and the periplasm. There are other important classes of proteins, including structural proteins and membrane-bound proteins, that have very few examples with their structures determined. Additional reasons for developing high-resolution solid state NMR spectroscopy of proteins include its ability to give an alternative view of these structures, its ability describe their structure and dynamics in an integrated manner, and its relaxed sample requirements compared with the standard methods for protein structure determination. In addition, there is no intrinsic size limitation for the polypeptides that can be studied by solid state NMR spectroscopy.

Although solid state NMR spectroscopy was established as an independent method for determining molecular structure at atomic resolution in 1948,¹⁰ only recently has it been used to obtain structural information that is completely independent of X-ray diffraction results, primarily because of the need to devise experimental methods capable of yielding spectra with sufficient sensitivity and resolution for observing resonances from individual sites in complex molecules like proteins. The basic physical properties of the various spin interactions are so well understood that spectroscopic interpretations have not been a limiting factor in applying solid state NMR spectroscopy to the study of proteins. A combination of biochemical and spectroscopic manipulations makes it possible to obtain spectra of proteins where resonances are resolved, assigned, and have spectral parameters from one of the spin interactions expressed in a defined way. The large amplitude, rapid motions of protein in solution average the chemical shift, dipolar, and quadrupolar spin interactions to their isotropic values, and only the indirect effects of their fluctuations through relaxation phenomena yield spatial information in the form of relative proximities. In contrast, in immobile proteins the rigid lattice values, as well as their angular dependencies, are directly observed.

The solid state NMR approach to determining the structures of peptides and proteins in oriented samples that we are most intensively involved in developing relies on the spectral simplifications that result from uniaxial sample orientation parallel to the direction of the applied magnetic field.¹¹ The spin interactions at individual sites yield single resonance lines characterized by their resonance frequencies or doublets (or triplets) characterized by the magnitudes (and asymmetry) of their splittings. The observed values of the frequencies and splittings depend on the orientations of the principal axes of the spin-interaction tensors present at each site relative to the direction of the applied magnetic field. Since the directions of sample orientation and the applied magnetic field are the

same, they define a frame of reference for the evaluation of the orientational information. The orientations of many spin-interaction tensors have been established in their molecular frames of reference, enabling angular factors to be determined from the experimental data.

The development of solid state NMR spectroscopy as a method for determining the structures of oriented macromolecules began in 1975–76 with the observation of high-resolution spectra from a polymer fiber oriented parallel to the direction of the applied magnetic field, and the determination of the angles between the C–H bonds and the fiber axis using separated local field spectroscopy to measure heteronuclear dipole–dipole couplings.¹² This initial study of a synthetic polymer demonstrated the feasibility of structural studies of biopolymers that could be prepared with uniaxial orientation.

THE APPLICATION OF NMR SPECTROSCOPY TO PROTEINS

Filamentous Bacteriophages

Much of the development of the method for determining the structures of oriented proteins by solid state NMR spectroscopy has utilized the favorable properties of the filamentous bacteriophages, the overall requirements of the proteins being immobile on the appropriate NMR timescales (10^3 – 10^6 Hz) and uniaxially oriented along the direction of the applied magnetic field. Filamentous bacteriophage coat proteins are particularly well suited for this approach, since the structured residues of the major coat protein are immobilized by interactions within the protein subunit, and the virus particles are so large and elongated that they do not reorient on NMR timescales. Remarkably, these virus particles orient spontaneously with their filament axis aligned with the direction of the applied magnetic field.

All of the structural studies of the filamentous viruses planned when the laboratory was being established at the University of Pennsylvania starting in 1976–79 were designed to take advantage of the fact that these nucleoprotein complexes could be oriented either as fibers, or later as solutions in the magnetic field of the spectrometer. By 1982–83 the implementation of selective ^{15}N labeling of both backbone and sidechain sites and magnetic orientation of virus solutions enabled the high-resolution structural information to be obtained on a protein in a supramolecular structure, the 10^7 kilodalton virus particles. Subsequently, ^{13}C and ^{15}N NMR experiments were used to obtain data from a sufficient number of sites to yield a model of the fd coat protein in the bacteriophage.⁶

Membrane Proteins

Membrane proteins are responsible for many of the properties and functions of biological systems. Determining the structures of membrane proteins is one of the most important challenges in the field of structural biology at the present time. Because of the continuing difficulty in crystallizing these proteins, it is essential that NMR spectroscopy be able to

study these proteins. Many of the technical difficulties associated with NMR studies of proteins in membrane environments can be overcome with a concerted approach, combining the methods of high-resolution solid state NMR spectroscopy on samples of membrane proteins in bilayers with those of multi-dimensional solution NMR spectroscopy on samples of membrane proteins in micelles. In this approach, the secondary structure of the protein is determined on the basis of inter-nuclear distance measurements in micelle samples and the arrangement of the major elements of secondary structure is derived from measurements of angular parameters in oriented bilayer samples.¹³

Overhauser, Albert W.: Dynamic Nuclear Polarization

Albert W. Overhauser

Purdue University, West Lafayette, IN, USA

INTRODUCTION

New ideas generally spring from cultivated soil, a state of readiness formed by the efforts and inspirations of mentors and colleagues. The discovery described below would not have occurred had Charles Kittel not assigned me a thesis topic to study all mechanisms that cause conduction-electron spins in metals to relax towards equilibrium. Spin-flip scattering induced by the orbital motion or spins of (other) conduction electrons, by lattice vibrations, by paramagnetic impurities, and by nuclear spins were all investigated.¹ Of minor importance was the last mechanism, caused by the Pauli hyperfine coupling between electron and nuclear spins.

My postdoctoral efforts at the University of Illinois were focused on radiation-induced defects in solids, a comprehensive program due to Frederick Seitz. However by 1951, Illinois had become a hotbed of magnetic resonance. Research activities of C. P. Slichter, R. E. Norberg, and H. Gutowsky kept alive my interest in spin dynamics which, perforce, had become a sideline.

Calculations of spin-lattice relaxation rates usually assume that all other components of the system remain nearly in thermal equilibrium. This approximation is frequently satisfactory, but any part of a system which is out of equilibrium will also drive other parts to deviate. Such phenomena were well studied by L. Onsager. Intuition suggests that if one component is out of equilibrium by, say, a per cent, other components will be forced out of equilibrium by a similar, small amount. It was quite surprising then to discover that if conduction-electron spins were driven out of equilibrium by 1%, the nuclear spin polarization could be enhanced by ~2000%.

One technique for disrupting electron-spin equilibrium is ESR, i.e. driving the spin resonance towards saturation. With a static field B_0 in the z direction and an rf field $2B_1 \cos \omega t$ in the x direction, the absorbed power P increases with increasing B_1 , but ultimately approaches a limiting value $P_{\max}$.

$$P = s P_{\max} \quad (1)$$

where the saturation factor s is

$$s = \frac{\gamma_e^2 B_1^2 T_1 T_2}{1 + \gamma_e^2 B_1^2 T_1 T_2} \quad (2)$$

The quantity γ_e is an electron's gyromagnetic ratio, $-2\mu_B/\hbar$ and T_1 and T_2 are the longitudinal and transverse relaxation times. At complete saturation ($s = 1$), up and down electron-spin populations become equal.

A nuclear spin S interacts with each conduction-electron spin σ through the Pauli hyperfine coupling, $\sim S \cdot \sigma$. This interaction conserves the total spin. Thus an out-of-equilibrium electron spin trying to flip down will occasionally do so by flipping a nuclear spin up. The induced steady-state polarization of nuclear spins, having gyromagnetic ratio γ_n , attains a value in the field B_0 as if the nuclei had an effective gyromagnetic ratio,²

$$\gamma_{\text{eff}} = \gamma_n + s|\gamma_e| \quad (3)$$

This remarkable result, derived below, predicts that for $s \sim 1$, the induced nuclear polarization will be ~2000-times larger than expected.

A discussion of this prediction was given at the Washington, DC meeting of the American Physical Society in April, 1953. The presentation went over like a lead balloon. A. Abragam, who was there, records the following account in his autobiography:³

To finish up with NMR at Harvard, I wish to mention another event which was to play an important part in my future activities: the Overhauser effect. Albert Overhauser, a young theoretician from the University of Illinois, had made the following prediction: in a metal, where the conduction electrons are known to be responsible for the nuclear relaxation, the saturation of the ESR resonance of these electrons should lead to an enormous increase in the nuclear polarization. I am not going to explain the meaning of this sentence here, for I will come to this problem later in the book. Right now I'll say two things. First, that this work provoked a delayed reaction in me which directed my thoughts on to a topic that was to preoccupy me for many years—namely “dynamic nuclear polarization”. Secondly, that Overhauser's audience at the meeting of the American Physical Society—where he had (in ten minutes) presented the calculations which had led to his amazing conclusion—was immediately split into two parts, which, however, overlapped: those who did not understand a single word of his demonstration, and those who did not believe a single word of his conclusions. In the first row of the sceptics who did not believe his conclusions shone all the stars of magnetic resonance: Bloch and Purcell, Rabi and Ramsey. Bloembergen was of two minds and so was I. As for the presentation itself, I will repeat what Van de Graaff had told me of de Broglie's defense of his thesis in Paris in 1924. “Never had so much gone over the heads of so many”.

The real question was of course: “Was Overhauser right?” He was: the proof of the pudding was given the same year by Charles Slichter, a physicist from Illinois, and his student, Carver. They saturated the resonance of conduction electrons in metallic lithium and saw the enhancement of the nuclear polarization predicted by Overhauser.

Most nuclei have positive γ_n . For these, equation (3) predicts an effective nuclear spin temperature smaller than ambient by $\sim 1/2000$. However for nuclei with negative γ_n , equation (3) implies that the nuclear spin temperature is first driven to infinity, and then deeply into the negative, ‘hotter than hot’ temperature regime.

CROSS RELAXATION

For clarity and simplicity the treatment which follows employs nuclei with $S = \frac{1}{2}$. Furthermore, the electron

concentration will be taken to be sufficiently small so that Fermi–Dirac factors (which recognize the exclusion principle) can be neglected. The general theory without these simplifications leads to dynamic nuclear polarization given by equation (3).⁴

Longitudinal (spin–lattice) relaxation of electron spins can be written,

$$\frac{dp_e}{dt} = -\frac{p_e - p_{e0}}{T'_{1e}} - \frac{p_e - p_{e0}}{T_{1e}p} \quad (4)$$

where p_e is the fractional spin polarization, $(n_{e\downarrow} - n_{e\uparrow})/n$; p_{e0} is its equilibrium value. Relaxation caused by the Pauli $\mathbf{S} \cdot \boldsymbol{\sigma}$ hyperfine interaction with nuclear spins, $1/T_{1e}p$, has been separated from $1/T'_{1e}$, caused by all other mechanisms. The $\mathbf{S} \cdot \boldsymbol{\sigma}$ term would be considered negligible in most contexts. Here, however, it is the only important term. The relevant effect of the dominant term, $1/T'_{1e}$ in equation (4) is merely to increase the required rf power needed for ESR saturation. With conduction electrons present, nuclear spin relaxation arises from the Pauli hyperfine coupling.⁵

$$\frac{dp_n}{dt} = -\frac{p_n - p_{n0}}{T_{1n}p} \quad (5)$$

It is convenient here to introduce out-of-equilibrium variables, D_e and D_n ,

$$D_e = n_e(p_e - p_{e0}) \quad (6a)$$

$$D_n = n_n(p_n - p_{n0}) \quad (6b)$$

which are both zero in thermal equilibrium. Cross relaxation between the electron and nuclear spin systems is easily introduced. For electron-spin relaxation,

$$\frac{dD_e}{dt} = -\frac{D_e}{T'_{1e}} - \frac{D_e}{T_{1e}p} + \alpha D_n \quad (7)$$

and for nuclear-spin relaxation,

$$\frac{dD_n}{dt} = -\frac{D_n}{T_{1n}p} + \beta D_e \quad (8)$$

where α and β are cross-relaxation coefficients, which arise from the Pauli $\mathbf{S} \cdot \boldsymbol{\sigma}$ coupling.

Since the $\mathbf{S} \cdot \boldsymbol{\sigma}$ interactions conserve total spin, the rates of change of the z components must be equal and opposite:

$$-\frac{D_e}{T_{1e}p} + \alpha D_n = -\left(-\frac{D_n}{T_{1n}p} + \beta D_e\right) \quad (9)$$

which after a mere rearrangement requires,

$$\left(\alpha - \frac{1}{T_{1n}p}\right) D_n = \left(\frac{1}{T_{1e}p} - \beta\right) D_e \quad (10)$$

Since this identity is valid for all, arbitrary values of both D_e and D_n , the cross-relaxation coefficients can only be:

$$\left. \begin{aligned} \alpha &= \frac{1}{T_{1n}p} \\ \beta &= \frac{1}{T_{1e}p} \end{aligned} \right\} \quad (11)$$

The relaxation of nuclear spins is now

$$\frac{dD_n}{dt} = -\frac{D_n}{T_{1n}p} + \frac{D_e}{T_{1e}p} \quad (12)$$

For any nonequilibrium steady state, e.g. during a continuous ESR excitation, equation (12) must equal zero. Accordingly,

$$D_n = \frac{T_{1n}p}{T_{1e}p} D_e \quad (13)$$

The importance of this result is evident. It reveals the out-of-equilibrium nuclear polarization D_n resulting from any imposed value of D_e .

NUCLEAR POLARIZATION BY ESR SATURATION

The ratio of the two relaxation times appearing in equation (13) can be calculated, for example, by golden-rule perturbation theory. The spin-flip rate of a nuclear spin is,

$$\frac{1}{T_{1n}p} = \frac{2\pi}{\hbar} |M|^2 \rho_e n_e \quad (14)$$

where M is the appropriate matrix element of the $\mathbf{S} \cdot \boldsymbol{\sigma}$ interaction and n_e is the number of electron spins with which each nucleus interacts. Similarly,

$$\frac{1}{T_{1e}p} = \frac{2\pi}{\hbar} |M|^2 \rho_n n_n \quad (15)$$

All common factors cancel when equation (15) is divided by equation (14). Accordingly,

$$\frac{T_{1n}p}{T_{1e}p} = \frac{n_n}{n_e} \quad (16)$$

which with equation (13) implies,

$$\frac{D_n}{D_e} = \frac{n_n}{n_e} \quad (17)$$

The fractional polarizations, p_e and p_n , can now be restored from equation (6).

$$p_n = p_{n0} + p_e - p_{e0} \quad (18)$$

Now, the rf power P absorbed by the electron spins is converted into heat by the electron-spin relaxation. From equation (1),

$$s = \frac{P}{P_{\max}} = \frac{p_{e0} - p_e}{p_{e0}} \quad (19)$$

equations (18) and (19) show that,

$$p_n = p_{n0} - sp_{e0} \quad (\gamma_n \text{ negative}) \quad (20)$$

The equilibrium polarizations p_{e0} and p_{n0} , defined to be positive, are (for high T) proportional to the gyromagnetic ratios γ_e and γ_n . Equations (6b) and (9) involved an implicit

assumption that γ_e and γ_n had the same sign. If γ_n is positive, equation (20) is replaced by

$$p_n = p_{n0} + sp_{e0} \quad (\gamma_n \text{ positive}) \quad (21)$$

Equations (20) and (21) agree with equation (3). However, the derivation just given is (unnecessarily) restricted to small deviations and high T .

It is necessary of course to examine the detailed mechanisms which cause the polarization enhancement in a way like that just presented. However it is not clear from such a treatment why the effect is so large. The fact that one electron-spin flip involves an energy change sufficient to flip $|\gamma_e/\gamma_n|$ nuclear spins does not by itself provide conviction. Kittel found an intuitive route which leads to equation (3) without any calculation whatsoever.⁶

The Boltzmann factors of a canonical ensemble, $\exp(-E/k_B T)$, arise from the entropy differences of the thermal reservoir. For nuclear spin up versus down, the reservoir energy differs by only a nuclear Zeeman splitting. However if a nuclear-spin flip occurs only in conjunction with an electron-spin flip, and the latter is immediately reversed by the saturating rf field driving the ESR, an electron's Zeeman energy, $2\mu_B B_0$, is effectively delivered (from the rf source) to the reservoir. Consequently the statistical weight of the reservoir is changed according to the sum of the Zeeman splittings, and the relative nuclear-spin populations respond accordingly.

Nonitinerant electrons, such as free radicals or paramagnetic ions can also be used for dynamic nuclear polarization.⁷ The important spin-spin coupling is then a (magnetic) dipole-dipole interaction. This interaction does not conserve total spin, so the maximum polarization enhancement is smaller by about a factor of three.

VERIFICATION

The first confirmation of the theory was an intellectual one. During the summer of 1953 I received the following letter from Ramsey:

July 27, 1953

Dear Dr. Overhauser:

You may recall that at the Washington Meeting of the Physical Society, when you presented your paper on nuclear alignment, Bloch, Rabi, Pearsall, and myself all said that we found it difficult to believe your conclusions and suspected that some fundamental fallacy would turn up in your argument. Subsequent to my coming to Brookhaven from Harvard for the summer, I have had occasion to see the manuscript of your paper.

After considerable effort in trying to find the fallacy in your argument, I finally concluded that there was no fundamental fallacy to be found. Indeed, my feeling is that this provides a most intriguing and interesting technique for aligning nuclei. After considerable argument, I also succeeded in convincing Rabi and Bob Pound of the validity of your proposal and I have recently been told by Pound that he subsequently converted Pearsall shortly before Pound left for Europe.

I hope that you will have complete success in overcoming the rather formidable experimental problems that still remain. I shall be very interested to hear of what success you have with the method.

Sincerely,

Norman F. Ramsey

Forty years later I found this letter in my file. I sent a copy to Ramsey as a remembrance of the encouragement he had provided to a young novice. His reply provides additional insight.

April 20, 1993

Dear Al:

I greatly appreciate your thoughtful remarks about the letter I wrote you forty years ago. Although I clearly remember surprising some of my friends by writing a very favorable referee report, I had forgotten that I also had written you a letter.

You might be interested in how I came to get the matter straight and avoid the lifelong embarrassment of being responsible for the rejection of a great pioneering paper.

After the APS meeting I did not understand your paper and was thoroughly convinced by the vigorous arguments of Bloch, Rabi, and others that a radiofrequency field always produces heating. I was consequently annoyed when I was asked to referee the paper and therefore would have to find exactly what was wrong. I started my study with strong prejudices against you but I then remembered that in high school physics I had always had trouble remembering how a Servel (gas) refrigerator worked. I decided that I could not write a negative referee report until I understood once again how the Servel worked. By the time I understood that, I had lost my prejudice against your paper and on further study was convinced you were right. Incidentally the easiest way for me to remember how in principle a gas refrigerator can work without violating thermodynamics is to remember one could use the heat of the gas flame to operate a steam engine which in turn could operate a mechanical refrigerator

Sincerely yours,

Norman F. Ramsey

The most direct experimental test of dynamic nuclear polarization utilizes double resonance. One must select a static field B_0 for which rf excitation of the ESR and measurement of the NMR can occur simultaneously. This difficult experiment was first attempted by Carver and Slichter in metallic lithium.⁸ They selected $B_0 = 30.3$ G, which required an NMR frequency of only 50 kHz. The ESR frequency was 84 MHz. Without the 84 MHz oscillation, no ^7Li NMR signal was visible. However with $B_1 = 5$ G (for the 84 MHz excitation), a large ^7Li NMR resonance appeared. On comparing the signal amplitude to the NMR of protons in glycerin (also at 50 kHz), the ^7Li NMR enhancement was estimated to be ~ 100 .

Hecht and Redfield later carried out precision measurements of the NMR enhancements in lithium and sodium.⁹ They worked at 1.5 K, where NMR relaxation times were long (~ 29 s in Li). The nuclei were first polarized in a small field, $B_0 = 10.4$ G. Subsequently B_0 was adiabatically increased to several hundred gauss, where the nuclear polarization could be accurately measured. Nearly complete polarization, according to the prediction of equation (3), was observed.

Dynamic nuclear polarization by ESR saturation has been studied extensively in nonmetals: liquid and solid diamagnetics, paramagnetic salts, semiconductors, alkali halide crystals, and alkali ammonia solutions.¹⁰

ESR FREQUENCY SHIFT

Polarization of nuclei in metals can also be confirmed by measuring the ESR frequency shift caused by the polarization.⁴ The Pauli paramagnetism of a metal produces an NMR frequency shift, i.e. $\nu_n = \nu_{n0} (1 + K)$, on account of

the hyperfine interaction between conduction electrons and nuclei.¹¹ The quantity K is the Knight shift. Values range from a fraction of a per cent to 2%. for lithium $K = 0.0249\%$. The same hyperfine interaction will cause an ESR frequency shift as the nuclei become polarized.

$$\nu_e = \nu_{e0} + Dp_n \quad (22)$$

where p_n is the fractional nuclear polarization. For lithium $D = 217$ G. One must work at low temperatures to maximize the shift Dp_n .

An interesting optical bistability is associated with this phenomenon. Suppose one sweeps the ESR frequency slowly upwards. As the ESR becomes excited, the center of the resonance shifts upwards as the nuclei become polarized. The maximum shift will of course depend on the rf power and temperature. When the maximum shift according to equation (22) has been reached, further increase in ν will cause the rf to cross over the ESR peak. Subsequently the dynamic polarization will be lost, and p_n will relax back to p_{n0} . The shifted resonance, equation (22), is attained only if ν is swept positively. A negative sweep will not encounter the resonance until it approaches ν_{e0} . All of these effects have been verified by Ryter.¹²

ESR saturation in a metal counteracts the Pauli paramagnetism and thereby suppresses the Knight shift. Pake has suggested that the ESR shift, equation (22), be called the 'day shift' since it dawns as the Knight shift subsides.¹³

Albert W. Overhauser. b 1925. B.A., 1948, Ph.D., 1951, University of California, Berkeley (supervisor Charles Kittel), Sc.D. (honorary), University of Chicago, 1979. Postdoctoral work at the University of Illinois. Assistant and associate professor, Cornell University; Manager, Assistant Director, and Director for Physical Sciences, Ford Motor Co., Scientific Laboratory; currently Stuart Distinguished Professor of Physics, Purdue University. National Medal of Science, awarded by the President of the United States, 1994. Research specialties: solid state theory, many-electron theory, broken symmetry in metals, neutron interferometry, superconductivity.

Packard, Martin E.: Nuclear Induction at Stanford and the Transition to Varian

Martin E. Packard

*Varian Associates, Palo Alto, CA, USA; Institute for Genetic Disease
Control in Animals, Davis, Davis, CA*

THE BEGINNING—EARLY JANUARY 1946

We glimpsed our first nuclear induction signal one chilly night in early January 1946. The term ‘nuclear induction’ was coined because we were looking for a small voltage induced in the receiver coil by the precessing nuclei. The ‘we’ were Professors Felix Bloch, William W. Hansen, and the graduate student, Martin E. Packard. It was chilly because the experiment was set up in the cyclotron laboratory which was in a leaky, unheated, glassed-over light well in the basement of the original sandstone quad of Leland Stanford Junior University.

The glimpse followed a fruitless two hours of adjustment as we tried to optimize the equipment and parameters to match the expected conditions for resonance. The experimental conditions were set on the assumption that the thermal relaxation time, T_1 , would be very long, perhaps days, and the transverse relaxation, T_2 , would be very short, corresponding to the dipole–dipole interaction of the neighboring protons.

For these reasons, the sample of ordinary water was ‘presoaked’, i.e. polarized for 24 h in a special outrider gap of the fringe field of the cyclotron, and the radiofrequency (rf) level in the probe adjusted to be a few gauss. The strength of the magnetic field was adjusted for resonance at a value corresponding to the rf frequency of 7.76 megacycles. The 4 or 5-in. magnet was connected in series with the cyclotron magnet, thus using the cyclotron power supply and regulator. The 60 cycle sweep was broad enough amply to cover the putative linewidth of about 5 G. The radiofrequency (rf) level in the probe was adjusted to be a few gauss and set to the resonant frequency by means of a surplus US Army frequency meter.

The sample was removed by Bloch from the fringe field of the cyclotron magnet and placed in the nuclear induction probe which was centered in the gap of the small magnet (Figure 1). Nothing was seen. As a last ditch attempt, the current through the cyclotron and small magnet was taken much higher than expected for resonance and allowed to drift downward at the slow rate determined by the time constant of the cyclotron magnet.

I was watching the oscilloscope screen and saw a weak signal move across the screen, much as one would expect a radar signal to do. The lineshape of the signal was unique in that it was positive on the right-hand side of the screen and negative on the left-hand side. The pattern was repeated,

Figure 1 The magnet and probe assembly of the first nuclear induction apparatus used by Bloch, Hansen, and Packard at Stanford, circa January 4, 1946. The knob turned the ‘paddle’ to balance out the leakage. The clamps held the laminated pole pieces

thus releasing the euphoria which comes to researchers when they finally succeed. Thus in a few brief minutes we were compensated for the work and disappointments of the previous three months.

It was quite clear that our earlier estimate of the thermal relaxation time was several orders of magnitude too high. During the next day or two Bloch reviewed his equations and had the explanation for what we had seen; he named the condition as adiabatic rapid passage. He understood the role of the rapid tumbling of the water molecules in reducing the thermal relaxation time, although he did not anticipate the beautiful description later developed by Nicholas Bloembergen.¹ Bloch often stressed how treacherous was the theory of liquids as contrasted to solids and gases. We were all happy that ordinary water had been the sample of choice.

A short letter to the Editor² was prepared and appeared in *Physical Review*, along with the results of Professor Edwin M. Purcell, Henry C. Torrey, and Robert V. Pound.³ The Nobel committee correctly overlooked this small priority of two weeks, as the two experiments were really conceived and implemented independently. The 1951 Nobel Prize in Physics was jointly awarded to Bloch and Purcell.

We might have been perhaps a week earlier had I not chosen to drive to Oregon to visit my parents over Christmas. I had not seen them for some time because of World War II.

PROLOGUE

The work of assembling the apparatus was started in late September 1945. However that was not the start of the project. Felix (we usually used his first name) told us the idea came to him during a concert which he attended while working with Professor Frederick Terman^{4*} at the Harvard Radiation Lab, not the MIT lab. A project he was working on involved finding a coating that would absorb rather than reflect radar signals; the precursor of the Stealth Bomber of the 1990s.

A question which is often asked is what is the origin of an idea. In Bloch’s story we will start with Professor Isador I. Rabi’s⁵ classical experiments. For several years Bloch had been focusing on measuring the value of the magnetic moment

of the neutron. He and Professor Luis W. Alvarez⁶ of the University of California at Berkeley carried out a measurement of the neutron moment in terms of the proton cyclotron frequency. The extension of this method to several nuclei required an accurate and less cumbersome way to measure the magnetic field.

Bloch, of course, was familiar with Professor Rabi's⁷ classical measurement of proton and deuteron moments in a molecular beam apparatus and with Professor C. J. Gorter's⁸ unsuccessful attempt to observe resonance in a very pure solid. Felix Bloch pioneered the method of polarizing thermal neutrons⁹ by passing them through a slab of magnetized iron. I was not aware of his early work in magnetism and the elucidation of the 'Bloch wall' until the arrival of the semiconductor age. Bloch's insight led him to a simple way of measuring magnetic fields by observing resonance in matter of 'normal density' as contrasted to the molecular beams of Rabi, an important step in expanding the measurement of nuclear moments. Conversations with Bill Hansen, while they were both at Harvard and later at Stanford, showed the feasibility of the idea and provided the practical basis for the apparatus.

Shortly after the Japanese capitulation in the summer of 1945, I was introduced to Professor Bloch by my Westinghouse supervisor and Stanford physics alumnus, Dr. Daniel Alpert. Our group had been sent from Pittsburgh to work on improving the mass spectrometer separation of uranium-235 for the Manhattan project. Our laboratory was next to the 184-in. cyclotron magnet in the hills above the University of California at Berkeley.

After listening to Professor Bloch explain his nuclear induction idea, I made an immediate decision to join his group, i.e. Bloch and Hansen. A week later my wife, Barbara, and I moved to Palo Alto and I was a graduate student and teaching assistant at Stanford. The admission procedure was more streamlined at that time.

The distribution of tasks was rather simple and required very little interaction between us.

Bloch prepared the magnet, starting with a small clumsy C-shaped lecture demonstration magnet. Laminated pole pieces were attached to allow the use of a large sinusoidal sweep for display of the signal. The magnetic field was measured with a conventional galvanometer and flip coil, the area of which could only be estimated to a few per cent.

Hansen designed and supervised the construction of the rf receiver portion of the system. This included the probe, the diode detector, and audio preamplifier. This was all contained in a brass box with an appendage, which we called the probe, that allowed the transmitter, receiver coils, and the sample to be placed between the pole pieces of the magnet. He also conceived and implemented the famous cross-coil configuration.

Bill Hansen was a genius in designing systems that would move but were not overconstrained, like linear motion using ball bearings in one V groove and a flat. He called this approach 'kinematic design'. His experience with the orthogonal nature of fields in microwave cavities and the decoupling needed in Doppler radar systems led him to decouple the transmitter and the receiver coil by making them orthogonal. Even at that he chose to use a diode detector without any rf amplification, to avoid saturation.

His first configuration, which used wires for constraints, allowed for rotation, but was sensitive to vibration and hence

Figure 2 This first nuclear induction probe was constructed by Hansen. The crossed wires provided kinematic constraints on rotation to achieve a geometric balance. The design proved to be noisy and was superseded by the 'paddle'

was too noisy. A redesign with the 'paddle' for flux steering was the solution (Figure 2).

My task was to design and construct the rf source, the audio amplifier, and the display, which was a DuMont 5-in. oscilloscope.

The jargon which developed came from our individual experience in the radar business. The techniques which we used were well known. We were familiar with the detection of weak signals in the presence of a strong source and the use of orthogonal decoupling. The sweep field reduced the $1/f$ noise by shifting from the dc region. The signal-to-noise ratio was derived from a calculation of the Johnson¹⁰ noise in the resonant receiver coil and the nuclear magnetization determined from the Boltzmann factor.

THE LULL AFTER THE FIRST SUCCESS

We moved the system into a room adjacent to the cyclotron and reassembled the system, without immediate success. Bloch was to present a talk on the experiment at the local weekly Physics Department colloquium. It seemed like a nice idea to show how simple the nuclear induction effect was by providing a demonstration as part of the talk. That was a mistake; I was unable to make it work, much to my embarrassment. Bloch in his usual nice way compensated for my confusion and lack of success.

THE BLOCH VERSUS PURCELL METHOD

At Stanford we viewed the phenomenon as one of expectation values which could be handled by classical mechanics and electrical theory, while Purcell viewed the phenomenon as a spectroscopic one with transitions taking place between the Zeeman levels.

The balance of the cross-coil system left only a quadrature leakage which selected for the out-of-phase component of the signal; thus we viewed the dispersion component. The balanced bridge of Purcell and co-workers favored the

absorption component. The initial experiments of Bloch and Purcell appeared to many to be quite different, whilst in reality the signals observed by the two groups were of the same phenomenon but only in quadrature to each other.

Strangely, this misconception persisted for a very long time.¹¹ Even 30 years after the initial experiments, I was challenged by a foreign visitor with the myth about the Bloch method and the Purcell method.

Bloch's equations proved to be the most useful approach for us in understanding the details of the nuclear resonances, particularly for steady state and pulses in the rotating frame.¹² However, the effects of spin-spin coupling required the spectroscopic approach to explain the observed splitting of the lines.

THE SCIENTIFIC DIRECTION OF THE LABORATORY

A review of many of the projects provides insight as to the main thrust of the laboratory and serves to identify the many able graduate students who obtained their Ph.D. degrees under Bloch.

Although the work of the laboratory was never highly organized and very few group meetings were held, Bloch had a simple objective and projects were selected to further that goal. He felt that the values of the nuclear moments of the isotopes would be important in understanding nuclear forces.

Neutron Measurements

In the paper with Luis W. Alvarez[†] prepared in 1939 on the neutron magnetic moment, the authors wrote: 'The now rather accurately known values ... of the magnetic moments of proton, neutron, and deuteron are of considerable interest for nuclear theory.' At that time, the deuteron moment was known to an accuracy of 1% to be the sum of the proton and the neutron moments. The accuracy was not high enough to test the theories rigorously. Higher accuracy would require a more accurate magnetic field determination, which Bloch later achieved with his nuclear induction method.

One of the first applications of nuclear induction was to improve the accuracy of the neutron moment measurement in terms of the proton. This measurement was done with the Stanford cyclotron by Professor Hans Staub, F. Bloch and Dr. D. Nicodemus.¹³ The magnet field was automatically stabilized accurately at the proper value for neutron resonance by a nuclear induction magnetic field controller¹⁴ which I devised and constructed.

The neutron experiments at Stanford and Berkeley had their genesis in the magnetic polarizing techniques proposed in 1936 by Bloch.⁹ One of the earliest neutron experiments was by Dr. Edward Fryer whose Stanford dissertation was on the cross-section of moderated neutrons.¹⁵ Ed Fryer was later to join Varian as manager of its Quantum Electronics Division, where he worked with magnetometers and frequency standards.

Emery Rogers, who later played a key role at Varian in building market acceptance by the chemists for the use of nuclear magnetic resonance (NMR), measured the sign of

the moment of the neutron and proton using the Stanford cyclotron.

The Nuclear Magnetic Moment Spectrometer of Hansen

Bill Hansen designed a spectrometer which was to automate the search for magnetic moments. Its most prominent feature was a table-top Bitter magnet, named after its designer, Professor Francis Bitter of the Massachusetts Institute of Technology. The automated nuclear induction spectrometer was dropped in favor of the individual creativity and labors of graduate students.

Warren Proctor's initial assignment was to work on the spectrometer. Warren eased himself out of this approach and went on to discover the nitrogen chemical shift with Dr. Fu Chun Yu^{16a,b} and to report on the magnetic moments of many isotopes. Bill Hansen[‡] devoted his remaining energy and life to demonstrating the electron linear accelerator. He had worked before the war on producing high voltages for an X-ray source. The rhumbatron, which was the heart of the klystron, was first demonstrated as part of a device for producing high voltages.¹⁷

The linear electron accelerator became the basis of SLAC. Dr. Henry Kaplan of the Stanford Medical School demonstrated its use for cancer treatment.¹⁸ Dr. Edward L. Ginzton at Varian Associates commercialized the small accelerator as the modality of choice for radiation cancer therapy.

Hansen died on May 23, 1949 at a young age from emphysema which many of us felt was caused by vapors produced while welding beryllium.

The Chemical Shift of Nitrogen

Warren Proctor and Fu Chun Yu[§] used a dissolved sample of ammonium nitrate as a source of nitrogen in their measurement of the nitrogen moment.^{16b} The resonance was found, but to our surprise and mild dismay consisted of two peaks, one for the NH_4^+ and the other for NO_3^- . This effect was quickly attributed to a diamagnetic shielding which was explained by Lamb,¹⁹ and later as a paramagnetic shift by Professor Norman Ramsey.²⁰

This chemical effect, which was to become the most important aspect of NMR for the chemists, forced a shift in the basic strategy of the laboratory. If the value of the magnetic moments was to be useful in nuclear force theory, the effect of the chemical shift must be removed.

Erwin Hahn and Spin Echoes

Dr. Erwin Hahn brought his beautiful spin echo technique^{21a-c} to Stanford from Urbana with the puzzle about the structure in the echo when observing organic liquids. Felix worked closely with Erwin on the theoretical aspects of the chemical structure in the echoes. Although the spin echo technique was elegant, it was not widely used until the advent of magnetic resonance imaging (MRI) which is now an important imaging modality in medicine.

Erwin's pulse technology pointed the way for observing NMR by the use of pulses to tip the spins. Russell Varian's proton free precession idea^{22a,b} was an alternative method of tipping the spins. Both concepts were preludes to Weston Anderson and Richard Ernst's pulsed Fourier transform methods.²³ The Fourier transform brought increased sensitivity and flexibility which was so important to the chemists and later for MRI. Richard Ernst received the Nobel Prize in Chemistry in 1991 for his work with Fourier transforms, which he started while at Varian Associates in 1962.

Other Moments and Graduate Students

Elliot Leventhal measured the magnetic moment of deuterium precisely in terms of the proton.²⁴ This experiment was the first to use a double tuned receiver and transmitter coil which allowed the use of two rf frequencies set to resonate simultaneously the nuclei of light and heavy water. Irradiating the sample with two frequencies become important to the chemist for magnet stability, calibration, and to control and identify spin-spin interactions.

Over the years, many nuclear magnet moments were observed by the graduate students. Proctor's early work was with nitrogen, but he reported on many other isotopes.^{16a,25a-c} Harry E. Weaver reported on 12 other isotopes.^{26a-d} Carson Jeffries measured the proton cyclotron frequency in terms of the proton moment,^{27,28} thus providing the link to the earlier neutron measurements of Alvarez and Bloch.

This interest in magnetic moments of other isotopes continued for several years even after several of us joined Varian. Dr. Arnold Bloom, who joined Varian in 1953 from the University of California at Berkeley, provided the values for the early compilation of nuclear moments in the 'CRC Handbook of Chemistry and Physics'. Following Bloom's departure in 1966 for spectra physics, the listing was extended by Weston Anderson and Dr. Kenneth Lee. The current table contains 115 isotopes that have been determined by nuclear induction.

One of Varian's early products was a variable tuned spectrometer for observing wide-line NMR signals in many isotopes. Harry Weaver became the product champion for this technology as well as Varian Associates' entry into electron paramagnetic resonance (EPR or ESR as it is known to many chemists). A stringent test for the sensitivity of the wide-line nuclear magnetic moment spectrometer was to measure the deuterium in ordinary water. The deuterium signal is nearly a million-times weaker than the hydrogen signal in ordinary water, as both the magnetic moment and the natural abundance are smaller.

One special case was our work with Mel Klein of the Livermore Laboratory on measuring the ratio of ⁶Li to ⁷Li in enriched samples.²⁹

The Tritium Experiment at Los Alamos

Professor Bloch arranged for us to measure the magnetic moment of tritium. This was during the winter of 1947, at

which time small samples of triply heavy water were classified and available only at the National Laboratories. My earlier Q clearance came in handy.

We loaded all of our apparatus into a truck and moved it to Los Alamos. The principal piece of equipment was the large C-shaped magnet, which was borrowed from UC Berkeley. This was the same magnet, or at least the coils, used by Ernest O. Lawrence in his early cyclotron experiments.

The apparatus had to be modified, which I was in no rush to do, as our six weeks stay in Los Alamos was very pleasant. The laboratory had not yet begun to take on its modern shape. We stayed in the original Fuller Lodge, and my wife Barbara had time enough to learn about the culture of the Pueblo Indians of Santa Clara and San Ildefonso. She collected many art objects which include several pieces of Maria Martinez's now famous black pottery.

Felix managed to spend one weekend skiing with us, where I appreciated his mastery of the European telemark turn.³⁰ On the trip back from the ski slope, I stopped and took a 16-mm movie of the beautiful scenery. A young soldier guard spotted me. I had some trepidation that this might have been a serious infraction of security, but nothing happened.

The actual experiment was simple and done quickly as we needed only to adjust the rf to provide for simultaneous display of the signals. The frequencies were measured with a surplus US Army frequency meter.^{31a-c} After the experiment was completed, R. Spence, the chemist, reported that the pressure, due to beta decay, in the fractional sample was higher than he had expected. I still wonder what would have happened if the experiment had been delayed and the sample ruptured. Al Graves was heavily irradiated by the accident which occurred when two ²³⁵U samples were gingerly moved together by hand to test criticality. We were not oblivious to the risks of radioactive materials and were careful, but not paranoid.

Sensitivity

The need for increased sensitivity was always present and remained a challenge. David Garber³² worked on a photographic technique for averaging multiple sweeps to reduce low frequency noise. The concept was sound but it was not applied until much later when Varian introduced the all-digital C-1024. At that time I was Division Manager at Varian and forecast that only 10 units would be sold. In actuality, hundreds were bought and used by the chemists.

Lineshapes

The accurate measurement of the resonant frequency required that we set the resonant condition well within the linewidth. As the resolution increased, we saw that the absorption lineshape was not a simple Lorentzian but asymmetric and followed by 'wiggles'. My solution was to follow our experience from the radar field and use a sine wave sweep and set on the center of symmetry. I

suggested this approach to Felix, who thought a moment and agreed.

The solution of the Bloch equations for the steady-state condition was trivial, but a real challenge for other conditions. Dr. Boris Jacobsohn and Rowald Wangsness³³ developed an analytical solution which included the wiggles. Years later Dr. Arnold Bloom tried to solve the equations using the big analog computer at Stanford, with no results. The machine lacked the necessary stability.

THE BEGINNING OF HIGH RESOLUTION

The sensitivity and the resolution improved steadily over the first years. Two of the standard experiments which were used to impress visitors were to observe the signal from a finger placed in the probe and to demonstrate one's strength by pressing on both sides of the C-configured magnet to cause the signal to shift across the oscilloscope screen.

Bloch's hope was that the true value of the magnetic moments could be determined by applying a calculated correction of the chemical shift. This seemed possible for the lighter isotopes but the precision had to be very high.

The All-New 12 in. Electromagnet

Harry Weaver was assigned the job of designing a magnet which would have larger pole pieces for homogeneity, a higher field for sensitivity, and a full yoke for stability. The windings were high impedance as the current was regulated using surplus modulators which had eight 304TL vacuum tubes.

This basic magnet design was used by Varian in all the high-resolution research NMR spectrometers until the advent of the superconducting magnet³⁴ which was also Harry's contribution to the chemist.

Helium-3

It was natural to try to measure the magnet moment of ³He as part of the effort to reduce or remove the effect of the chemical shift. Again it was hoped that calculations, particularly of the lighter isotopes, would allow a correction to give the true magnetic moment.

Bloch obtained a very small sample of ³He. I blew the glass for the sample-handling system and prepared the sample vial filled with FeO₂³⁵ as a means of reducing the relaxation time. The sample vial was evacuated and the helium transferred. It remained for H. L. Anderson³⁶ to provide the value, as we saw no signal. Whether this was due to the very small sample or to a flaw in the relaxation process we never knew.

Harry Weaver's big 12 in. electromagnet was placed in service sometime during 1950. James T. Arnold, a graduate student, and I set out to utilize its size and field strength to improve sensitivity and resolution to measure the magnet moments of the light isotopes better and to correct for the effect of the surrounding electrons.

With these narrow lines, hence low rf fields and better decoupling between the transmitter and receiver coils, we chose to use an rf amplifier. The leakage was adjusted to present the absorption mode. The operating frequency was

chosen to be 30 Mc s⁻¹ (MHz) because that was the frequency of the surplus radar intermediate frequency (if) strips. Stanford science benefitted from the mountain of surplus gear which was scattered about the old and condemned dormitory, Sequoia Hall. Thirty megahertz and 7000 G became the de facto standard for several years.

The pole pieces of the magnet were not finely machined or polished, which was somewhat of a blessing. Jim Arnold became a master at moving the probe within the gap to find a local region of high homogeneity. We tried some rudimentary electric shimming to improve the homogeneity. It remained for Dr. Edwin Jaynes³⁷ to provide the theoretical basis for the orthogonal electric shims and for others to make them practical by moving them from a spherical geometry to the flat pole pieces.^{38a-d}

Another major improvement in homogeneity came with the spinning sample idea of Bloch's which was successfully demonstrated by Arnold and Anderson.^{39a-c} Bloch reported that the idea came to him as he was stirring a cup of tea midday at home!

HIGH RESOLUTION IN ORGANIC COMPOUNDS

The Alcohol Experiment

Although we were able to measure the shifts, for example, between water and mineral oil, the standard of groups in the East,⁴⁰ this was set aside following the suggestion of Dr. Shrinvas Dharmatti, a postdoc from the Tata Institute in Bombay. He asked what would happen if we looked at an organic liquid.

We first tried ethyl alcohol, which was one of our favorite substances, and were rewarded with the view of three separate peaks. This led us to publish a comparison of the area under the peaks in various alcohols. This paper, although not important in itself, attracted considerable attention.^{41a-d} It was this picture which later brought Dr. James Shoolery⁴² to Varian, an event which contributed so much to the development of NMR spectroscopy for and by the chemists.

Felix Bloch did not choose to place his name on the seminal high-resolution paper of organic compounds even though it would have been appropriate. Although he never objected to our foray into chemistry, that was not his major interest.

The spectrum shown in the first alcohol paper was deliberately broadened by selecting an inhomogeneous spot in the magnet, but with great care we could observe three lines in the methyl group and four in the methylene group. The hydroxyl group remained only one peak (Figure 3). This splitting was the result of the spin-spin coupling which turned out to be so important to the chemists as it provided information about the number and closeness of near neighbors.

Hydrogen Bonding of the Hydroxyl Group in Alcohol

An important demonstration of the intermolecular exchange was noted by Jim Arnold who observed that the separation between the hydroxyl and methylene peak was temperature dependent. This we did not understand and decided to publish a short letter describing the effect. We were very quickly

Figure 3 An early slide of the NMR spectrum of ethanol showing the splitting of the peaks caused by the spins of the adjacent protons. The sweep was repeated to reduce artifacts and was reversed from contemporary standards. The 'wiggles' following the peaks are the free precession transients due to a too fast sweep

rewarded with the answer by U. Liddel and Norman F. Ramsey that the effect was explained by the hydrogen bonding between the hydroxyl groups of the alcohol molecules.^{41b,c} Norman Ramsey contributed to the art of cesium and hydrogen frequency standards. He was later elected to the Board of Varian Associates.

This simple explanation of hydrogen bonding for the temperature effect prompted Bloch to show me how a two peak pattern becomes one under conditions of rapid exchange. The split powder peak of George Pake** became one line with molecular motion.⁴³ This averaging effect provided the insight basic to the spin-spin decoupling methods,⁴⁴⁻⁴⁶ and even the spinning sample method of line narrowing.

Second-Order Splitting

Jim Arnold single handedly built a large permanent magnet to provide better short time stability. With this magnet he observed and calculated the spectra using second-order perturbation theory. Weston Anderson joined Arnold and determined several organic spin coupling constants and chemical shifts by fitting them to an exact quantum mechanical model.^{47a-c}

This magnet was taken to CERN, where Arnold and Anderson joined Bloch who served one year as its Director General. The magnet now reposes in the Smithsonian's large collection of early NMR artifacts.

Acceptance by the Chemists

Even though we were physically close to the Stanford Chemistry Department, our work attracted little attention on the campus. Professor Richard Ogg was our principal visionary supporter of the embryonic technique.^{48a-c} This is not to say that the chemists were not cooperative. We relied on

the chemistry store room and occasional help with chemistry which was beyond our capabilities. Professor Harry Mosher remembers preparing an exotic compound for Erwin Hahn to use in testing some proton-exchange ideas.⁴⁹

RUSSELL VARIAN AND THE PATENT

From time to time I had discussions with Russell Varian, whom I knew as the inventor of the klystron. I knew about klystrons from my radar days and of Stanford's role because I inherited a corner of the old empty upstairs klystron lab in which to build the nuclear induction apparatus.

Although I was not aware of it at the time, Russell was preparing a patent application which was subsequently to be one of the cornerstones of the start-up company, Varian Associates. Russell's belief in and understanding of patents stemmed from his early work and perhaps was influenced by his uncle who was a patent attorney. Russell and his brother, Sig, started a research laboratory, the products of which were to be practical inventions.⁵⁰ Russell had gained wide experience over the years in preparing patents. He prepared some patents on geophysical equipment while working at Humble in Houston, he contributed to the klystron patent at Stanford, and he honed his claim-writing expertise while at Sperry. The klystron patent was to return money to the Varian brothers and to Stanford. The Varian Physics Building at Stanford had its genesis from Varian's share of the klystron royalties.

The inventors of nuclear induction, Professors Bloch and Hansen, were of the school that believed that science was done for science's sake. It was reported later that both Bloch and Hansen laughed at the idea of patenting the nuclear induction experiment. At that time, conflict of interest between industry and universities was not of great concern. Nevertheless, Russell's efforts, buttressed by Ed Ginzton, prevailed, and the patent was filed and assigned to the nascent Varian Associates. Without this modicum of monopoly, it would have been financially unrewarding for Varian to develop the instruments needed by the chemists.

Russ was experienced and effective in writing claims. The patent was contested by a major instrument firm only on the basis of prior art, citing Zavoisky's publication in Russia. Depositions were taken from Bloch, me, and others, but the case never went to the courts.

Although it was thought by the founders of Varian Associates that nuclear induction could be the company's main product, it turned out otherwise. The founders had considerable experience with klystrons, both theoretical and practical. The timing was right to obtain government and commercial contracts for new and rugged klystrons, both small and very large. Without this financial support the history of NMR might have been much different.

EPILOGUE

Support by the Office of Naval Research (ONR)

After the initial experiment, the laboratory was generously and wisely supported by the Office of Naval Research (ONR). At that time the research could only have been classified

as basic research with no foreseeable use by the Navy. In fact this was not the case. The high-resolution technology which stemmed from the early work on nuclear forces was of inestimable value to the Navy in solving chemical problems. We were grateful that Professor Walter Meyerhof, who had newly joined the Stanford Physics Department, shielded us from the administrative chores of the ONR contract.

The ONR support continued at Varian as the more fundamental ideas were applied to practical problems. Thus, Russell Varian's invention of the proton free precession magnetometer led to the standard Navy magnetometer for antisubmarine warfare (ASW) applications. The final version used the optical pumping of Professor Hans Dehmelt of the University of Washington and the helium improvement of Professor Peter Franken. Optical pumping is also the basis of atomic frequency standards used for applications such as the global positioning system (GPS).

We were grateful to the ONR experts, who had the vision to support very basic research and were rewarded with many practical solutions to society's needs.

Confluence of Ideas, People, and Environment

The period following the end of World War II in 1945 was unusual. The universities were just beginning to get back into action, the students and professors were well trained in the latest technologies coming from the war effort, and were highly motivated.

Stanford was an attraction for many because of the impressive intellectual and physical environment. These were the conditions which spawned what became known as Silicon Valley. Small entrepreneurs started companies to exploit the ideas presented by the academic community. The relationship between Stanford and Varian was a classic example. Varian prospered on three ideas from Stanford, the klystron, NMR, and the linear accelerator.

Technology Transfer

Technology transfer was achieved, long before it became articulated and fashionable, by the movement of students from the university laboratories to industry.

My role as a physicist working with NMR continued when I went to Varian in the fall of 1951. I had remained as an instructor at Stanford after achieving my Ph.D., as well as our first born, in the summer of 1949. My duties involved both research and the teaching of advanced courses, which I enjoyed. The Physics Department had a wise policy that restricted the addition of recent Stanford Ph.D.s to the staff. I had to make a decision between leaving for academia or industry. I choose Varian Associates, a decision which I never regretted.

My opportunity at Varian was to develop, under ONR sponsorship, another of Russ's ingenious ideas. This we called the 'black box' because it was classified by the Navy. It was to be a moving target filter for doppler radar. The concept of using quantum mechanical systems for circuit applications was sound, but the NMR signal-to-noise ratio was not high enough to make it practical. Nevertheless, the

Figure 4 Martin Packard and Russell Varian with the first free precession Earth's field magnetometer. This provided an accurate measurement of the Earth's total field in terms of a frequency. The proton sample is the bottle of water in the foreground

task stretched our technology which was then applied to other problems.

Subsequently, I worked with Russ on still another of his ideas, the free precession magnetometer (Figure 4). This idea led Varian Associates into geophysics, oil-well logging, airborne and ground-based magnetometer surveys, antisubmarine warfare (ASW), and stable atomic frequency sources used in satellite-based navigation systems.

The knowledge of basic magnet resonance was effectively transferred from Stanford and other universities to the marketplace by the movement of graduate students to Varian. Although I have written primarily about the Stanford students, the contribution of students from other universities was equally important (Figure 5).

The Chemists Take Over

The physicists at Stanford made their contribution to the art of NMR but were in no position to bring the ideas to the marketplace where the technique could be used to solve problems arising in other disciplines, chemistry, biology, and medicine.

The glimpse of molecular configuration in the alcohols demonstrated the potential of the method, but would not be useful to the chemists without further development. Its development required a multidisciplinary approach, with the physicists continuing to develop the technology, the chemist

Figure 5 Technology was transferred from the university laboratories through the graduate students. From left to right, Martin Packard from Stanford, Richard Sands from the University of Michigan, and Professor Bloch discuss a topic at the workshop held by Varian for visiting scientists

Figure 6 Forrest Nelson, a Varian Engineer, shares his expertise with workshop participants. Forrest was responsible for many of the innovative ideas

providing the applications, and the engineers building the instruments, either singly or serially (Figure 6).

The year 1951 was the time for the chemists to take over from the physicists. However, at that time we never could have predicted that three decades later a chemist, Professor Paul Lauterbur,⁵¹ would turn the technology over to the medical clinicians for noninvasive imaging.

Nature was Most Benevolent

Nature was most helpful in supplying the ubiquitous hydrogen nucleus with spin- $\frac{1}{2}$ and a large magnet moment.

Man's intellect in developing the basic mathematics and computers, and his insatiable curiosity and drive to make use of Nature's gifts, led to developments of great use to mankind throughout the world.

Very few scientific concepts have had such a long period of new and important applications as has nuclear induction, known as nuclear magnetic resonance (NMR) to the chemist, and magnetic resonance imaging (MRI) to the physician.

NOTES

*Professor Terman's contributions to the Stanford Industrial Park and what came to be known as 'Silicon Valley' are discussed in Ref. 4.

†Alvarez facetiously but proudly told me that Bloch's knowledge of experimental techniques came from his readings during the experiment.

‡Hansen has been quoted by Pieff Panofsky and others for his famous 1947 one-line quarterly report: 'We have accelerated electrons'.

§At the time of writing (1994), Professor Yu is still active although retired from the Physics Department of Beijing University. Science in the Physics Department at Stanford was truly international in its participation.

**George Pake was to become the chairman of the Stanford Physics Department and later to direct the Xerox Laboratory at Palo Alto, which spawned the mouse and the Macintosh computer concept.

Packer, Ken: Connections (or One Thing Leads to Another)

Ken Packer

University of Nottingham, Nottingham, UK

In 1960, whilst pursuing preparative inorganic chemistry research for my doctorate, I made a new compound. In establishing that the structure of this was $\text{SF}_5\text{OSO}_2\text{F}$ I had the ^{19}F NMR spectrum run on the department's Varian 40 MHz V4300 spectrometer. The spectrum was complex and, as I knew little of NMR at the time, I turned to Norman Sheppard. He realised that this spectrum was an excellent example of an AB_4X spin system. The theory of these spin systems was being worked on by one of his students, Robin Harris, and our collaboration in analyzing these spectra¹ kindled my enthusiasm for NMR and, of course, set the scene for further collaboration with Robin later in our careers whilst at the University of East Anglia (UEA). A postdoctoral fellowship at DuPont, with the late Earl Muetterties, generated the ^{19}F and ^{93}Nb NMR spectra of the NbF_6^- ion² which got me interested in relaxation processes. Soon after returning to a post at UEA I realised that sharing a high-resolution spectrometer with preparative chemists was not going to allow me to pursue my developing interests in the more physical aspects of NMR. I was fortunate enough to persuade those controlling the funding of research that a pulsed NMR spectrometer was just what I needed so, in 1965, I found myself the proud owner of a Magnion pulsed NMR spectrometer which I combined with a 4 tonne AEI electromagnet.

In telling this personal story I hope to demonstrate how different aspects of one's research experience often interconnect. One of the areas which fascinated me at this early stage was the use of gradients in magnetic fields to allow transport processes such as diffusion and flow to be characterized.³ This is still an active interest today. Our early work on flow had as a goal the design of a pulse sequence which would determine the flow character in a single shot. Carr and Purcell had shown that flow through a gradient only gave rise to effects on odd echoes of their multipulse echo sequence, which made it like a series of sequential two-pulse echo sequences. After much deliberation I realised, from an analysis of the phase shifts, that the phase of the magnetization had to be reversed more frequently which led to the $90^\circ - t - (180^\circ - t')$ sequence.⁴ In a lecture at the 8th International NMR Colloquium held in Aachen in 1971 I recall presenting this work, including an analysis of the alternating rf phases required for the 180° pulses to minimize cumulative errors. As I was describing this aspect, which had taken me considerable effort to work through, I happened to glance at John Waugh, sitting in the front row, who made a gesture indicating the solution to this problem, solved I imagine as I spoke!

The demonstration by Ed Stejskal and John Tanner of the effectiveness of pulsed gradient experiments encouraged me to explore the area of restricted diffusion and the quantitative determination of droplet sizes in emulsions. In our paper in 1972 we noted that the long-time limiting behavior should

allow the determination of the droplet size distribution through variation of the gradient pulse area.⁵ This was noted by colleagues in Unilever and we subsequently developed an approach based on this suggestion.⁶ The point of this story, however, is that at that stage we certainly did not recognise that there was a straightforward analogy of this behavior with optical scattering and diffraction with the gradient pulse area playing the role of a wavevector. Although the relationship between NMR in a gradient and diffraction was pointed out by Peter Mansfield in 1975, it was only when we commenced modeling the response of the pulsed field gradient spin echo experiment to the diffusion of molecules through porous media that the analogy became clear. Collaboration with Paul Callaghan on both theory and experiment added to our understanding of this phenomenon which is now widely recognised.⁷ In retrospect it is interesting to note how 20 years of thinking about this experiment made it hard to accept that the echo signal could increase as the gradient pulse area increased!

My involvement with diffusion measurements led to work on biological tissues, but that's another story. However, this led to an interest in NMR of dynamically ordered systems and it was in this context that I learnt an important lesson. Satapah Ahmad was a new student from Malaysia. As a project, I suggested that he measure the T_2 behavior for D_2O in an oriented system for which the ^2H spectrum was a simple doublet and indicated that he should use the Ostroff-Waugh sequence, $90^\circ_x - t (-90^\circ_y - 2t)_n$, as this should refocus the secular quadrupolar interaction at each echo. After some time Satapah came to me and showed me his results which indicated that $T_2 > T_1$. Naturally, I was not impressed! After several repeats by him of the measurements with the same outcome I carried out the experiments myself and got the same results! Clearly, a lot of knowledge is a dangerous thing! We subsequently developed a density matrix theory treatment which explained this behavior and, in addition, showed how it was possible to obtain all three spectral densities determining the relaxation behavior in such a system despite it being in extreme narrowing.⁸ A further outcome of my interest in this area was the development, with Kevin Wright, of a single spin operator formalism with which to describe the response of small spin systems with secular couplings to general pulse sequences.⁹ It was on a plane journey from Melbourne to Canberra that I learnt from Geoffrey Bodenhausen that Richard Ernst's group had also been developing a similar approach. This was both good and bad news simultaneously! Our description of the generalized behavior of the AX spin system in the form of a topological framework was a particular pleasure to me.

Of course, the ultimate in terms of secular spin couplings are those in a many-spin rigid solid. When Gibby, Pines, and Waugh and Schaefer and Stejskal showed the way, Robin Harris and I recognized that our complementary experiences placed us in a strong position to contribute to this, then emerging area of high-resolution NMR in solids. Thus began a decade of challenging and fascinating research taking us from spectrometer building, engineering of cylindrical gas bearings for sample spinning and a range of new NMR phenomena, into a wide range of applications in chemistry and materials.¹⁰

In finishing this brief retrospective I recall some advice I was given when I was considering moving into NMR research as a graduate student who thought he had 'seen the (NMR)

light'. This was to the effect that NMR was pretty well developed and understood and did not have much more to offer a keen young researcher. That was in 1960! Predicting the future was never easy!

Introduced to NMR by making a new compound and collaborating with fellow graduate student (Robin Harris) in the analysis of its spectrum. Reinforced by a postdoctoral year with Earl Muetterties at the duPont Experimental Station, Wilmington. 1963–84, School of Chemical Sciences, University of East Anglia; 1984–93, BP Research, Chief Research Associate in Spectroscopy and latterly Chief Scientist. Currently, Research Professor in Chemistry, Department of Chemistry, University of Nottingham. Approx 120 publications including book 'NMR of Solid Polymers' with V. J. McBrierty. Current research interests: NMR/MRI applied to heterogeneous catalysts, solid polymers, and fluid transport processes in porous solids.

Pake, George E.: A Graduate Student and Young Faculty Physicist Wanders into NMR: 1946–53

George E. Pake

Institute for Research on Learning, Palo Alto, CA, USA

Enrolling as a graduate student in the Harvard Physics Department in 1946 was a piece of extraordinary good fortune that arose from several chance decisions at forks in my personal educational road. It was extreme good luck because I happened into Harvard just as Edward Purcell and his colleagues Bob Pound and Nicolaas Bloembergen were launching their pioneering research program in NMR, and I became one of the first Harvard graduate students to join Purcell's research group. In fact, I believe I was the first; Bloembergen, whose thesis research with Purcell preceded mine, was in fact a University of Leiden student doing his doctoral research at Harvard because European universities were only just beginning to restore normal graduate programs in early 1946. American universities had been less severely disrupted by World War II and could resume graduate operations much more rapidly.

I had received my M.S. in Physics from Carnegie Institute of Technology (now Carnegie–Mellon University) in April 1945, and I then took up employment during those wartime years at the Westinghouse Research Laboratories in East Pittsburgh, developing microwave components for airborne radar systems. With World War II in full swing at the time (although the imminent defeat of Germany was evident, from all the news reports of the Nazi war machine being crushed between the Atlantic Allies' forces from the west and the Soviet hordes from the east), there were few if any truly active academic Ph.D. programs in Physics. The sensible procedure for an aspiring physicist at that time was to join the war effort in a way that used my physics training up to that point, awaiting the conclusion of hostilities to resume graduate study.

Although the decision to take a research position with Westinghouse was geographically convenient, it also turned out to be a real boost to my physics education. Microwave physics had not previously been mentioned in my studies, and I arrived at the Westinghouse labs to find a marvelously lucid set of lecture notes ('Principles of Microwave Radio', 1944, unpublished) by Edward Condon, then Associate Director of the Westinghouse Research Laboratories. I was given these notes and a development task to specify and test the design of an X-band (3-cm wave) directional coupler for an airborne radar. Further, I was urged to design and build an apparatus for measuring breakdown potentials of microwave gas discharges. From these tasks I learned several concepts and techniques which were later to be of value to me as a graduate student taking up research on NMR.

Other than some help that I provided in the low-temperature laboratory for Prof. I. Estermann at Carnegie during my

masters degree studies, the microwave work at Westinghouse was one of my earliest laboratory research experiences, and building the gas discharge apparatus represented my first independent experimental effort. The apparatus was just producing its first gas discharges (but no measurements yet) in August 1945 as the Pacific war ended. I immediately wrote to graduate physics departments to apply for admission to a Ph.D. program. With advice from my Carnegie Department Chairman, Prof. Fred Seitz, I applied both to Princeton and Harvard, planning at that time to pursue a thesis in theoretical physics. Activity in my Westinghouse Laboratory was stymied by a strike and a picket line of laboratory technicians, so my gas discharge apparatus was unavailable to me for several weeks, until suddenly it was time to leave for Harvard (my choice because it offered me a teaching fellowship, and I had no funds otherwise to support my further graduate study).

Also influencing my selection of Harvard was a handwritten letter from J. H. Van Vleck, then chairman of the Harvard department, warmly inviting me to come to Harvard under a teaching fellowship. I arrived in Cambridge in late January 1946 and began with a heavy dose of graduate courses.

During that semester, I attended two physics colloquia that captured my interest: one (in February, I think) by Ed Purcell, just returned to Harvard as Associate Professor of Physics, on the Purcell–Torrey–Pound experiment which in late 1945 had just detected nuclear magnetic resonance absorption in bulk matter (paraffin). A little later (I guess in April, in close association with an American Physical Society meeting in Cambridge), W. W. Hansen of Stanford gave a Harvard physics colloquium on the Bloch–Hansen–Packard nuclear induction experiment.

Purcell's talk was deeply inspirational to me. Here was an experimental physicist who demonstrated real appreciation of theory and of the consequences of his research for all of physics, both theory and experiment. I thought to myself, 'Why confine one's interest to theoretical physics if one can join a group that operates within the entire sphere of physics, both experiment and theory?' The Purcell–Torrey–Pound experiment also appealed to my recent microwave experience, as the paraffin proton resonance was detected in a resonant cavity (of course, at 30 MHz, not exactly in the microwave range, but using concepts familiar to me from my Westinghouse work).

There were other attractions: Purcell exhibited his characteristic lucidity and deep insight into physics as he spoke. And, of course, I felt some of the excitement of being 'in on the ground floor' of a new technique in physics. I was also imbued, like many of my graduate student colleagues, with a sense that with the war over we should all pitch in to develop an understanding of the nucleus and nuclear forces comparable to our post-World War I understanding of the atom. With the capability of NMR to provide a rich set of measured nuclear spins and magnetic moments, I saw it at first as a tool for nuclear physics. In the summer of 1946, most of the course work for my Ph.D. being completed, I applied to and was accepted into Purcell's research group.

I was assigned a laboratory room in the basement of the Lyman Laboratory, adjoining the room in which Nico Bloembergen was using a large electromagnet to pursue for his thesis project with Ed Purcell the pioneering investigation of nuclear magnetic relaxation in liquids. That research became, of course, the basis for the world famous BPP paper in the *Physical Review*.¹

Because the NMR lines could be very sharp, it was desirable to have a stable magnetic field. Purcell had decided to try out the efficacy of a fairly large permanent magnet. After it was magnetized with Purcell's help, this magnet became the central piece of my research apparatus. As I began to assemble a 30 MHz spectrometer for use in my experiments (by this time we were using lumped parameter resonant circuits, not cavities), I also engaged in serious planning for what my experiment should be. This of course involved numerous conferences with Purcell as my supervising professor, and I also had several informal discussions with Bob Pound and Nico Bloembergen.

Bob Pound at that time was pursuing his own researches on NMR line splitting in crystals, focusing particularly on nuclei of spin $I > \frac{1}{2}$ and their electric quadrupole splittings due to interaction with the gradient of the crystalline electric field. Pound was widely regarded as the group's electronics wizard. Whereas he surely had those skills in abundance, one should not overlook his deep comprehension of physics generally. As I was planning my thesis project, Bob Pound provided me with several valuable insights on nuclear magnets within crystal structures, which of course were the objects of his NMR studies of nuclear quadrupole interactions. Whereas Bloembergen and I operated fixed frequency rf spectrometers and swept the H_0 field in small excursions through the NMR resonance, Pound kept his magnetic field fixed and, using a clock motor to drive a variable capacitor, systematically swept the frequency of his marginal oscillator resonance detector over a wide range encompassing the sometimes rather large quadrupole splittings. These pioneering experiments were described in his *Physical Review paper*.²

I also had many talks with Nico Bloembergen, who was readily available to me in the laboratory adjoining mine. A special feature of the common wall between our laboratories was a large hole about 1.5 ft. by 3–4 ft. through which I could shout questions at Nico whenever I needed experimental guidance or, often times, just to discuss physics.

Bloembergen was progressing in his investigations of nuclear relaxation in liquids, and he had quickly observed that the lines were sharp, with their width being determined by the spatial inhomogeneity over the small ($\sim 1 \text{ cm}^3$) volume of the samples he used. This seemed to imply early on that the relative motions of the protons in water, for example, were averaging away the local dipolar magnetic fields which at any given instant ought, by calculation, to be several gauss. In discussing this with Nico, the idea arose: why not look in solids, such as the crystalline hydrates, to see what the linewidths are for protons of water molecules rigidly bound into the lattice? After discussion with Purcell, I pursued this line of investigation seeking to understand in detail the factors determining NMR linewidths in crystalline solids. The next question was: which solid hydrate(s) should I investigate?

The most frequently encountered crystalline hydrate in my science education up to that point was $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, which every student seemed to deal with in freshman chemistry as a source for the blue cupric ion in aqueous solutions. Also, it was relatively easy to grow single crystals from solution. However, for my purposes, the incomplete electron shells of the cupric ions render them paramagnetic, and the 2000-times larger Cu^{2+} ion magnetic moment would greatly perturb the tiny nuclear magnetic moments in its vicinity, making copper

sulfate a poor candidate for studies of purely internuclear magnetic interactions.

Never having had any formal instruction in geology, I picked up an introductory text and looked for a likely naturally occurring hydrate crystal. One immediately caught my attention: gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$. By virtue of the fact that even-even nuclei have zero nuclear spin in their ground states, the abundant isotopes of Ca, S, and O are all magnetically inert in gypsum, leaving only the pairs of water molecule protons to interact with each other and with neighboring pairs. This seemed ideal for my projected studies, but I had no idea how easily I could obtain a suitable single crystal. Upon crossing Oxford Street from the Lyman Laboratory to visit the Harvard Department of Mineralogy and Petrography, I found myself standing next to a gypsum crystal perhaps a meter long!

A kindly professor gave me a smaller gypsum single crystal from which I cut two samples about the size of my little finger. The cleavage planes were readily identifiable and there was little problem in establishing the unit cell axis directions using the known crystal structure.

Upon searching for the proton resonance in the gypsum crystal, I found immediately that the linewidth was strongly dependent upon crystal orientation in the external magnetic field, H_0 . From the presumed hydrogen nuclear positions based upon the structure as determined from X-ray diffraction (which permitted only educated inference of the likely hydrogen atom positions, as there is no electronic X-ray scattering from the protons), I was able to cut a crystal that, upon rotation in the magnetic field, permitted me to align H_0 either perpendicular to the line joining partner protons in the H_2O molecule, or nearly parallel to it. Systematic recording of the proton resonances versus crystal orientation showed resolvable pairs of resonance lines, presumably arising from the two alternative orientations (spin up or down) of the partner proton in each H_2O molecule. A crude semiclassical estimate of the local magnetic field component experienced at each proton from its partner's magnetic moment aligned along or against the external magnetic field led me to estimate a splitting between the pair of resonance lines to be

$$(\Delta H)_{\text{est.}} = (\mu/r_0^3)(3 \cos^2 \theta - 1) \quad (1)$$

where μ is the proton magnetic moment, r_0 the interproton distance in the water molecule, and θ the angle between H_0 and the interproton line.

However, a quantum calculation allowing for the indistinguishability of the two magnetically equivalent proton spins within the spin triplet state gives the angular dependence and the magnitude of the splitting of the pair of resonance lines. This quantum perturbation calculation found that equation (1) underestimates the magnitude of the splitting and that a factor $\frac{3}{2}$ should be supplied to the right-hand side of the equation to give the correct splitting. This was a great relief to me, in as much as the observed splittings if interpreted using the uncorrected equation (1) would lead to a value of r_0 that seemed quite unreasonably small in view of the existing knowledge of the H_2O molecular structure in the gaseous state.

When I first did the perturbation calculation, I had just been learning about unitary transformations in a class with Prof. J. Schwinger, and I was apparently obsessed with unitary transformations. Beginning with the spin functions corresponding

to eigenstates for $m = +\frac{1}{2}$ and $m = -\frac{1}{2}$ along the external magnetic field H_0 , I formed the symmetric combinations for spin triplets, and then used unitary transformations to rotate axes through angle θ to the direction of the interproton line. Using these new functions and treating the magnetic dipole–dipole interaction between partner protons as a perturbation, I laboriously worked out the energy level shifts and obtained the splitting of equation (1) with the correct $\frac{3}{2}$ factor. This was a very ‘round-about’ and needlessly cluttered approach to the problem.

The next day I went over my tedious 12 or 14 pages of handwritten algebra with Ed Purcell, who the following morning showed me an operator identity from which the correct splitting could be deduced in about two lines of calculation: perhaps one-third of a page in total.

About four or five months later, Purcell came to my laboratory with a short visitor, introduced as Prof. E. Fermi of Chicago. Asked to explain my experiment to the visitor, I began with the crude semiclassical estimate of the partner proton magnetic field, whereupon Fermi glanced at the ceiling, muttered something about equivalent protons and, after a few seconds of thought, said, ‘of course, the actual splitting will be $\frac{3}{2}$ of the semiclassical estimate’. To this day, I regard that experience as a somewhat accurate calibration of Pake’s relative theoretical ability: Fermi, 10 seconds; Purcell, less than half a page; Pake, 12 or 14 tedious pages. No; I am sure those ratios overestimate Pake’s ability by an order of magnitude or two. And they are unfair to Purcell, who doubtless only needed his one-third of a page in order to explain to me a calculation he made almost instantaneously.

Once I understood the gypsum single crystal splittings, I looked at a number of other hydrates, some of which I was only able to obtain in powdered form. This led me to deduce the obvious consequences of summing the resonance patterns of numerous randomly oriented microcrystals each exhibiting proton pair splittings that varied as $3 \cos^2 \theta - 1$. The resulting lineshape distribution is a characteristic doublet that is just barely resolvable in consequence of the broadening of each pair’s pattern by the effects of the more distant neighboring pairs.³

Because the gypsum research project went so smoothly, I found myself with a nearly completed thesis in February or March of 1948, with my degree award scheduled for June Commencement. In the meantime, through conversations that Ed Purcell had with Prof. George Kistiakowsky in Chemistry, I was introduced to one of Kisty’s students, Herbert S. Gutowsky, and together that spring and summer we used a copper-block cooling apparatus as a kind of cryostat for studying proton resonances in molecular van der Waals solids. These solids, even at temperatures near 100 K or 150 K, exhibited proton line narrowing that was evidence of hindered rotations either of whole molecules or of single-bonded radical groups attached thereto. From the amount of dipolar linewidth narrowing, we were able to interpret the nature of some of these rotations. We reported this research in a series of papers.^{4–6} These experiments, for me, nicely filled a gap between my thesis project and beginning to organize my own laboratory as I took up my first faculty position in the autumn of 1948 at Washington University in St. Louis.

In late July 1948, I drove from Cambridge to St. Louis and began to build up my magnetic resonance laboratory at Washington University. The Physics Department under A.

L. Hughes had an interesting and nearly unique policy of assigning each incoming graduate student immediately to a research group, which provided a sense of belonging and an early immersion in a research environment. As a consequence, after I had completed my thesis defense exam at Harvard and motored to St. Louis, I found myself called upon to transform from graduate student to research professor for seven graduate students. These eager young men were of great assistance as we began tooling up for research in the new field of magnetic resonance—although these students had noticeably less time for the lab once graduate course instruction reached full momentum that fall. There was, however, one major problem: the research field of NMR was so new in 1948 that no textbooks or treatises yet existed, and first-year graduate students typically had an inadequate background to read and comprehend the few published research papers, which in any case tended to be not very complete. While awaiting delivery of newly-ordered equipment for our laboratories-to-be, my students and I held a series of seminars in which I set forth background material for NMR research—being mindful that I could not yet assume a real working knowledge of quantum mechanics. These lectures I wrote up into a longish review article later published in the *American Journal of Physics* in two parts.^{7,8}

I was continually besieged with reprint requests, inasmuch as these beginning-level articles seemed to meet a clear need for individuals worldwide who wished to learn about this new technique. Because I quickly exhausted my supply of *AJP* reprints—and because xerographic technology was only just about to be, but not yet, marketed—I arranged with the American Institute of Physics for Washington University to do a half-scale photo-offset reprinting of these articles. As I recall, we distributed somewhere between 2000 and 5000 of these reprint sets in response to requests.

These articles even attracted some rather recent attention when Prof. Robert H. Romer, Editor of the *American Journal of Physics*, nominated them for a listing of outstanding *AJP* articles over the past several decades (see *Am. J. Phys.*, 1991, **59**, 201).

With my fledgling group of graduate students at Washington University, we made some progress on applying NMR to a number of areas of interest in physics. Here I would note as follows: the electric quadrupole moment of ${}^6\text{Li}$ ⁹ and the spin of ${}^9\text{Be}$,¹⁰ measurements by N. A. Schuster; early application of NMR to the study of polymers¹¹ by Charles W. Wilson III; radiofrequency measurements of relaxation times for electron spin resonances in free radicals¹² by J. P. Lloyd.

This first mention of free-radical molecules is an indicator of a change in direction for my research interests, largely a consequence of collaborations begun with Prof. S. I. Weissman of the Washington University Chemistry Department. While I was launching my NMR researches at Washington University in 1948 and 1949, Sam Weissman would often appear at my office or laboratory to discuss the potential of magnetic resonance as a technique for studying stable free-radical molecules. I was intrigued, inasmuch as I had not even heard of these stable molecules having unpaired electrons in nonconformance to the simple rules I had learned in my elementary chemistry classes. Since these electronic magnetic moments were much larger than the nuclear moments studied heretofore in my research, free-radical experiments would often require higher frequencies in the microwave range. The

more Weissman and I talked, the more promising these avenues of research seemed, and we enlisted Dr. Jack Townsend who built several spectrometers for our early free-radical studies. Weissman and his students went on to pursue an active and stellar program of magnetic resonance studies of free radicals.

One particular free radical supplied to my own researches by Weissman's group enabled some experiments that were, for me, quite aesthetically pleasing. These involved the peroxyamine disulfonate ion, $\text{ON}(\text{SO}_3)_2^{2-}$, in solution. Note that the abundant nuclear isotopes of this ion are all, except for ^{14}N , even-even and therefore have zero nuclear moment. This leaves just the ^{14}N nucleus of spin 1 to interact magnetically with the unpaired electron whose wavefunction is somehow draped over the ion. Surely enough, as expected, the microwave electron paramagnetic resonance in moderately large laboratory magnetic fields is a triplet corresponding to the three nuclear spin orientations accessible to ^{14}N , with the hyperfine coupling being about 54 or 55 MHz.

What I found so appealing about this ion is that, with its radiofrequency hyperfine coupling, we had in a small sample tube of ions in solution the magnetic analog of the atomic magnetic moment as studied in the early molecular beam experiments. To the extent that the analogy was valid, the energy levels of our free radical ion system in a magnetic field should be governed by the Breit-Rabi calculation,¹³ upon which rested interpretation of many of the historic molecular beam experiments, which had themselves helped to inspire the invention and detection of NMR. I therefore found enormous satisfaction in our radiofrequency investigation of the low magnetic field absorption spectrum of the $\text{ON}(\text{SO}_3)_2^{2-}$ ion,¹⁴ which neatly fitted the Breit-Rabi energy levels for an unpaired electron in hyperfine interaction with a ^{14}N nuclear moment having hyperfine coupling $\Delta\nu = 54.7$ MHz.

In a way that I found irresistibly appealing, my personal sojourn through the early years of NMR had brought me full circle to Breit-Rabi, upon which so much of molecular

beam physics had rested, and which therefore provided the foundations for NMR and electron paramagnetic resonance (EPR)—the fields upon which my own research career had been focused.

Pfeifer, Harry: Leipzig, Summer 1951

Harry Pfeifer

Universität Leipzig, Leipzig, Germany

The first nuclear magnetic resonance experiments performed at the University of Leipzig in the summer of 1951 were stimulated by events that took place 24 years before. In the fall of 1927 Peter Debye had moved from the Swiss Federal Institute of Technology at Zürich (ETH) to Leipzig where he became Director of the Institute of Experimental Physics and where he had persuaded Werner Heisenberg to accept the Professorship for Theoretical Physics (Figure 1). It was not surprising, therefore, that Leipzig became an attractive place for young scientists and students of physics. Among them the most prominent was apparently Felix Bloch, who writes in his 'Reminiscences of Heisenberg and the Early Days of Quantum Mechanics':¹ '... in October 1927 before the beginning of the winter semester, I left my nice home town (Zürich) for the first time to arrive on a cold gray morning in that rather ugly city of Leipzig ... As soon as I had completed the simple formality of registering as a student of the University in the center of the city I went to the Physics Institute, which was located near the outskirts. It was an old building opposite a cemetery on one side and adjoining the garden of a mental institution on the other, but occupied by people who were far from being either dead or crazy ... Debye had the Director's villa in a side wing, and for young bachelors like Wentzel and also Heisenberg upon his arrival there were small but comfortable apartments under the roof ... These men were so entirely devoted to their science and their work spoke so clearly for itself that there was really no room or reason for any pretence, be it in the form of grand manners or false modesty ...' In the following months Felix Bloch became the first doctorand of Werner Heisenberg, and he finished his thesis on 'The Quantum Mechanics of Electrons in Crystal Lattices' in 1928. After one year as an assistant to Pauli in Zürich and another year as Lorentz Fellow in Holland, Felix Bloch came back to Leipzig as Heisenberg's assistant in the fall of 1930 until Hitler succeeded in 1933 in forming a new Germany in his own frightful image.

After the war, in October 1947 when I came as a student for the first time to Leipzig University, the famous Institute of Physics 'located near the outskirts' in the Linnéstrasse 5 was only a ruin (Figure 2). The large auditory, the Director's villa, the large store rooms of scientific apparatus and most laboratories were completely destroyed. As a result, lectures were delivered at the Institute of Mathematics about one mile away where some rooms were also placed at the disposal of physicists including the Director's office and the library. Fortunately, nearly 80% of the scientific books and journals were saved since the Physics Library was housed in the tower of the Institute which survived the bombs due to its internal stability. In the ruin however, rain was destroying more and more of the remaining laboratories and the mechanical workshop, and I remember that in spite of the fact that all electrical equipment had been switched off, we observed a permanent electrical current of nearly 10 A at the main line supplying the ruin.

Nevertheless it was an exciting time of renewal, and at the end of the 1940s we received all the issues of *Physical Review* which could not be delivered before due to the war and afterwar problems. About that time Artur Lösche (b 1921) had finished his thesis on birefringence induced by mechanical rotation of polar liquids and became an assistant at the Institute of Physics. Being responsible for the library, he organized a systematic study of these journals. During this study he became aware of the exciting experiments of the former Leipzig scientist Felix Bloch, and in the summer of 1950 A. Lösche suggested the search for nuclear induction signals including preliminary experiments as a suitable topic for a diploma thesis. At this time I was students' assistant for the lectures in experimental physics delivered by the Director of the Institute, Professor Waldemar Ilberg, a physicist who had changed after the war from the electronic industry to university. He proposed the study of the light efficiency of gas discharge lamps since this would be a problem of special importance for an industry which was beginning to start at this time from a very low level in Germany. As a young student, it was not very easy for me to come to a decision but finally I chose the 'entirely useless' search for signals stemming from the Zeeman energy of hydrogen nuclei. There were two further students, Hans Lippmann and Karl-Heinz Weber, who also followed the suggestion of Dr. Lösche, so that we three started separately in September 1950 to find the nuclear induction signals which were described for the first time in 1946 independently by Felix Bloch et al. and E. M. Purcell et al. in the January issue of the *Physical Review*.^{2,3} For my studies I used an old electromagnet that had survived the bombardments of the institute (December 4, 1943, February 19, 1944, and April 6, 1945) and with the direct current supply commonly available in Leipzig at this time it was possible to achieve a magnetic field of about 0.8 T with a gap width of 2 cm. Stimulated by a paper by A. Roberts⁴ I decided to build a superregenerative detector and in this connection to study the nonlinear theory of electric oscillations established more than 20 years previously by van der Pol.⁵ As a result of the latter studies it could be shown theoretically⁶ why harmonic electric oscillations can be generated in the case of parallel resonant circuits only through a combination with a device whose negative differential electric resistance is achieved from the positive values via infinity, while for the other type of resonant circuits where the capacitor is in series with the inductance, the differential electric resistance must be zero at the transition from plus to minus. These considerations, however, did not help as much as some hints that I received from A. Roberts as a response to a letter that I wrote to him concerning practical aspects of the superregenerative detector. At the end of June 1951—I do not know the exact date, but I remember that it was in the late evening—I was looking at an oscilloscope at the output of the detector and listening simultaneously to a loudspeaker parallel to it. Suddenly I heard a growl when I varied the magnetic field around a certain value. Apparently it was caused by the 50 Hz modulation of the direct current of the electromagnet and, as it should, the growl ceased immediately after removing the small glass tube containing a dilute aqueous solution of iron chloride from the magnet: it was the first nuclear magnetic resonance signal at that place which Felix Bloch had left in 1933. Unfortunately, when the Director of the Institute, who had heard of the experiment, came to the ruin at the Linnéstrasse 5 to see the

Figure 1 The Physics Institute of the University of Leipzig before the war. The view is from the Linnéstrasse. On the right-hand side, the villa of the Director (1927, Peter Debye) can be seen; on the left-hand side is the large auditory and behind it the tower that housed the Physics Library

NMR signal, I could not reproduce it. I was very ashamed, but fatherlike with a slight smile on his face he said, ‘Oh, I do know this effect very well, we called it several years ago the “Vorführeffekt” (demonstration effect)’. Of course a few days later I observed the NMR signal again and started a systematic study that finally led to my diploma thesis.⁷ In the following year, the other two students also succeeded (diploma theses of H. Lippmann 1952 and of K.-H. Weber 1953), and Dr. Lösche published the first original paper on NMR in German with the title ‘Kernparamagnetismus und Hochfrequenztechnik’.⁸ In the same year the first publication reporting on successful NMR experiments performed at the Charles University, Prague by Pekárek and Urbanec appeared⁹ and also a theoretical paper by Chuzishvili from the Georgian Academy of Sciences in Tbilisi concerning the interaction between spins and lattice vibrations in crystals.¹⁰ The results of the first NMR studies performed in the former Soviet Union were published by Gvozdover and co-workers from Moscow^{11,12} and by Kozyrjev and Rivkind from Kazan.¹³ In 1953 another review by A. Lösche was published¹⁴ and two original papers appeared in German about proton magnetic relaxation in liquids by Krüger from Stuttgart¹⁵ and about the measurement of the intensity of the Earth’s magnetic field by NMR.¹⁶ One amusing point is that in the latter paper the editor had changed the symbol $\varnothing$ for the unit Oersted to the abbreviation Dmr for diameter so that the author and the readers of the paper were surprised to find that the total intensity of the Earth’s magnetic field at Leipzig had been

measured by NMR to be 0.475 ± 0.078 ‘diameters’. In 1954 the first paper on NMR studies performed in Hungary was published by Farago et al.,¹⁷ and a short note by W. Müller-Warmuth from the University of Frankfurt/Main appeared about an electronic device of the bridging type for measuring NMR signals.¹⁸ Since then, as in other countries, the number of NMR papers from Germany has increased substantially and a complete survey can be found in the book ‘Kerninduktion’ which was published by A. Lösche¹⁹ in 1957, being the third monograph on nuclear magnetic resonance spectroscopy that appeared after the well-known books of Andrew²⁰ and Grivet.²¹ From March 31 to April 2, 1960 the first German conference on rf spectroscopy was organized at Leipzig, and in 1961, only a few weeks after the wall was built in Berlin, the Tenth Colloque AMPERE (after Paris 1952, Grenoble 1953, Paris 1954, Paris 1955, Geneva 1956, St. Malo 1957, Paris 1958, London 1959, Pisa 1960) took place in Leipzig, with A. Lösche as chairman of the organizing committee.

The present position of nuclear magnetic spectroscopy in the Department of Physics of the University of Leipzig is characterized by the application of NMR methods in five main directions of research:

(1) *Liquid Crystals*. These studies go back to H. Lippmann and K.-H. Weber, the former students of A. Lösche who had already published a paper on this topic in 1957.²² A review of the more recent results in this field is given by Grande et al.²³

Figure 2 The Physics Institute after the war. The view is parallel to the Linnéstrasse. In the ruin on the right-hand side, in front of the tower, the first NMR signals in Leipzig were observed in the summer of 1951

(2) *Polymers*. Initiated by W. Holzmüller who after the war in 1952 returned to Leipzig from the Soviet Union. Polymer science was for many years one of the main areas of research at the Institute of Experimental Physics. At present, mainly polymeric layers²⁴ and polymer solutions²⁵ are being investigated.

(3) *Lipid Membranes*. These systems have been studied in Leipzig as models for biological membranes since the end of the 1970s by NMR and also by X-ray, neutron diffraction, infrared spectroscopy, and calorimetric methods (see, for example, Klose et al.^{26,27}).

(4) *Structural Phase Transitions in Solids*. In close cooperation with the University of Saarbrücken (J. Petersson) these investigations have been undertaken on single crystals of dielectrics and ferroelectrics as well as with systems of incommensurate phases.²⁸ In addition to NMR methods, various techniques of electron spin resonance including transient ESR have also been applied to these systems.

(5) *Solid Surfaces and Adsorbed Molecules*. After the initial investigations which were concerned with nuclear magnetic relaxation of molecules adsorbed on silica²⁹ and on γ -alumina,³⁰ the present studies are based on more informative NMR methods such as, for example, solid state high-resolution measurements^{31,32} and pulsed field gradient

techniques^{32,33} including infrared spectroscopy and inelastic neutron scattering. The systems under study are exclusively porous *crystals*, i.e. solids with a definite and well-known surface structure, such as zeolites or molecular sieves which have found widespread application in science and industry. The usefulness of NMR spectroscopy in this field was recognized by the presentation at the Seventh International Zeolite Conference in Tokyo 1986 of the Donald W. Breck Award to the Leipzig group,³⁴ this award having been established by the International Zeolite Association in 1983 to be presented for the most significant contribution to molecular sieve science and technology during the previous three years.

Current research specialty: application of NMR spectroscopy to the study of surface phenomena.

Pines, Alexander: Solid State NMR: Some Personal Recollections

Alexander Pines

University of California at Berkeley, Berkeley, CA, USA

I was born in 1945, the same year as NMR. I grew up in Rhodesia and then went to Israel to pursue my undergraduate studies in mathematics and chemistry at the Hebrew University of Jerusalem.

In 1968 I journeyed to the United States and entered the Massachusetts Institute of Technology (MIT) as a graduate student. There I was fortunate to work under the tutelage of John Waugh in the Department of Chemistry and the Research Laboratory of Electronics. It was an exciting time to be at MIT, and Waugh as well as postdoctoral co-workers from those days—among them Robert Griffin, Ulrich Haeberlen, Michael Mehring, and Won-Kyu Rhim—have remained my colleagues and friends for more than 25 years.

The MIT group's primary efforts at that time were directed toward the new area of multiple pulse and high-resolution NMR spectroscopy in solids. Waugh's accomplishments in average Hamiltonian theory and line narrowing were establishing much of the basis and the very language of modern pulsed NMR. The idea was to manipulate the spins by trains of pulses in order to average the spin interactions selectively—for example to eliminate dipole–dipole couplings while retaining the underlying chemical shifts, a sort of spin alchemy.

Participating in the study of coherent averaging and the challenging experimental techniques of multiple-pulse spectroscopy, including the magic sandwich time-reversal experiments (which appeared to violate the spin temperature hypothesis), was a stimulating educational experience for me, but it was natural to wonder if there might be an alternative way to observe chemical shifts in solids. An appealing prospect was the organic chemists' nucleus, carbon-13, which offered the possibility of resolved Fourier transform spectra in solids, owing to the isotope's low natural abundance and correspondingly weak dipole–dipole couplings. There would be no need for the demands of homonuclear multiple pulse sequences, and high power proton spin decoupling would suffice to eliminate the relevant heteronuclear couplings, but we anticipated that sensitivity might pose a problem. Here, however, we could capitalize upon the double resonance scheme of Hartmann and Hahn, whereby two different resonant frequencies are matched in the rotating frame, allowing the exchange of magnetization between different spin species. The process of cross polarization (CP) from abundant hydrogen to dilute carbon-13 combined with spin decoupling would allow us to enhance the sensitivity and resolution of the directly observed carbon signal.

The idea seemed promising, and we proceeded to design and construct a double resonance spectrometer with a PDP-12 controlled pulse programmer and data system. The experiments also required a novel probe that would allow cross polarization and direct observation of the enhanced carbon-13 signal in the presence of high power proton spin

decoupling. What we needed now was an appropriate model sample. It so happened that the late Henry Resing (known affectionately as Mr. Adamantane because of his work on plastic crystals) was visiting, and I asked him what would be an inexpensive compound (solid at room temperature) with at least two inequivalent carbon sites, but with the molecules reorienting rapidly and isotropically (in order to eliminate the chemical shift anisotropy) to yield laboratory and rotating frame spin–lattice relaxation times of about one second. He suggested adamantane.

Indeed, we were elated to observe resolved isotropic carbon-13 chemical shifts in solid adamantane, with ample signal/noise. We subsequently obtained resolved spectra allowing the measurement of carbon-13 chemical shift anisotropy in solid benzene and many other compounds, as well as signals from other dilute isotopes such as nitrogen-15 and silicon-29, leading some innocent bystanders to believe that high resolution solid state NMR of dilute spins might actually become useful in chemistry. We termed the technique proton-enhanced nuclear induction spectroscopy (proton-enhanced NMR for short) as a salute to the early foundations of nuclear induction laid by physicists. Combined with magic angle spinning (MAS), a legacy of Andrew, Lowe, and co-workers, incorporated by Schaefer and Stejskal soon after, the cross polarization/magic angle spinning (CP MAS) procedure was subsequently implemented and used on commercial spectrometers. Recent applications of CP MAS have included the possibility of measuring carbon-13 isotropic–anisotropic shift correlations through variable angle correlation spectroscopy (VACSYS) as well as the measurement of carbon–carbon and carbon–hydrogen dipolar correlations for the purposes of distance and structure determination in solids.

On completing my Ph.D. in 1972 I was awarded a Miller Fellowship in physics sponsored by Erwin Hahn at the University of California, Berkeley. Shortly afterwards, however, the Berkeley Chemistry Department offered me a faculty position, which I accepted, but not without some regret at passing up the opportunity to work directly with Hahn. Happily, Hahn, together with Mel Klein, has remained a mentor, colleague, and friend for more than two decades.

Over the years, our group at Berkeley (the so called Pinenuts) has been concerned with fundamental phenomena in NMR and chemical physics, hoping to develop techniques of some use in condensed matter chemistry and physics. Our work has involved a combination of concepts, theory, techniques, instrumentation, and applications to a variety of chemical systems and materials. Advances in spectral resolution, sensitivity and selectivity have remained consistent goals. I have been fortunate to work with, and learn from, a group of extremely talented and creative co-workers at Berkeley, including graduate students, postdoctoral fellows, and sabbatical visitors, some of whom are listed in Table 1; they were the ones who did the research and my story is largely theirs. In addition to research, I have devoted much time and effort to teaching. Beginning in the 1970s with advanced courses in physical chemistry, I was later persuaded by my colleague George Pimentel to take over the introductory general chemistry class which I have taught, on and off over the years, to many thousands of students. Both the freshmen and my research group, with their broad curiosity and their drive to understand the principles and beauty of science, have kept me alert and have enriched my academic experience. We

have continued to remind each other to refrain from the narrow path, not to hesitate to ask why and how, and never to accept simply on authority that something is impossible.

Our work at Berkeley in the early 1970s continued to deal with theoretical and experimental aspects of spin dynamics and solid state NMR, in particular the question of total adiabatic polarization transfer, the measurement of chemical shift tensors in single crystals, and the effects of symmetry-restricted motion on carbon-13 lineshapes in solids. The experiments required a homebuilt spectrometer (this time under the control of a new generation PDP-8 based pulse programmer and data system) as well as considerable effort in completing the superconducting joints, shim coils, and cryogenics of our primitive magnet. We also became intrigued by liquid crystals, for which we were able to use the carbon-13 tensors to study molecular ordering and phase transitions.

During that time, my colleague Charles Harris was also involved in magnetic resonance experiments that exploited the enormous sensitivity of optical detection to observe continuous wave electron paramagnetic resonance (EPR) microwave spectra in excited triplet states of molecular crystals. Because of the different rates of phosphorescence from the three triplet sublevels to the single ground state, microwave generated transitions between the sublevels could generate a change

in the phosphorescence signal by rearranging the sublevel populations, in analogy to continuous wave electron–nuclear double resonance (ENDOR). The detection of time domain signals, however, was a different matter—it was considered to be impossible because triplet sublevel coherences did not affect the populations and were therefore invisible to the phosphorescent emission; indeed, the detection of free induction decays and spin echoes in excited triplet states was traditionally performed only by direct microwave detection, with limited sensitivity. After pondering the possibility of applying optical detection to observe the spin coherence, we hit upon a solution that involved an additional read pulse, with which we were able to detect electron spin free induction decays and spin echoes through their effect on the optical emission. It was an early example of coherence transfer by transformation of the off-diagonal elements of the density matrix in order to map out the evolution of a perhaps invisible or hidden coherence, point by point.

What we learned from these experiments soon proved useful in the multiple quantum NMR experiments that followed. Our original intention was to study hydrogen NMR in solids, to provide an alternative to homonuclear multiple pulse sequences, this time by diluting protonated samples with deuterium. The idea was reminiscent of the approach

taken earlier with carbon, and here again there was a heteronuclear interaction that needed to be decoupled. The hydrogen–deuterium coupling, however, seemed futile to average because the wide, quadrupolar broadened deuterium line would require prohibitive radiofrequency power, but it was conceivable that we could exploit double quantum decoupling which had recently been used by Meiboom and co-workers in liquid crystals. Indeed, narrowband irradiation of the (+1, −1) transition of the deuterium with modest power yielded a resolved hydrogen spectrum, and in this way we could

observe the chemical shift anisotropy of hydrogen in ice—a notoriously difficult system for homonuclear multiple-pulse techniques. This approach has also been useful for obtaining resolved hydrogen dipole–dipole couplings and, combined with MAS, is an alternative approach to high-resolution hydrogen NMR in solids.

The next question, which emerged from our double quantum decoupling work and our previous experience with indirect detection of invisible microwave coherences, involved the possibility of preparing and observing, in the time domain,

the forbidden deuterium double quantum transition. Related work was being done independently by Hashi and co-workers. Having developed an appropriate spin-1 formalism involving fictitious spin-1/2 operators, we learned how to excite and detect the seemingly invisible two quantum coherence, point by point, by means of soft double quantum pulses (or pairs of hard pulses) combined with coherence transfer read pulses. Since the double quantum superposition should evolve independently of the quadrupole coupling, its spectrum would, in principle, reveal the deuterium chemical shift buried beneath the enormous quadrupolar broadening. By sidestepping rather than attempting to average the quadrupolar coupling, we were thus able to measure the chemical shift anisotropy of hydrogen in solid benzene. Various manifestations of double quantum coherence followed directly, including double quantum spin locking, cross polarization, spin diffusion, and magic angle spinning.

The spin-1 theory and experiments revealed the two-fold sensitivity of double quantum coherence to resonance offsets and radiofrequency phase shifts—double quantum spin locking, for example, was accomplished with a forty-five degree phase shift. Shortly thereafter, we provided an extension, namely the n quantum phase shift, to multiple quantum coherences in coupled spin-1/2 systems; this allowed a number of developments, including the separation of coherence orders (beginning with the progressively simplified spectra of orders zero through six in oriented benzene) by time proportional phase incrementation (TPPI), selective excitation of n quantum spectra (despite the arguments of some authorities that selective excitation was not possible), iterative multiple quantum sequences, multiple quantum filtering, imaging, relaxation and diffusion schemes, heteronuclear multiple quantum coherence experiments, bilinear rotation decoupling (BIRD), scalar (isotropic) recoupling, and total coherence transfer. The use of time-reversal sequences made it possible to produce two-dimensional schemes with symmetrized (conjugate) preparation and mixing propagators, yielding pure in-phase signals and allowing the observation of high n quantum spectra (sometimes in excess of one hundred quanta) and spin counting in liquid crystals and solids. We were delighted to see many of the multiple quantum ideas incorporated into high-resolution multidimensional liquid spectroscopy as well. For N spins, the high order ($N-1$ and $N-2$) spectra turned out to be particularly useful for the determination of molecular structures and conformations. Some of the experiments required the application of thousands of pulses, bringing to my mind the comment of Hahn when he heard about the original dipole–dipole time-reversal experiments—With that many pulses I could bring back the Messiah.

Three other areas that occupied our attention during the early 1980s were the magnetic isotope effect (through which we were able to obtain noticeable enrichments of carbon-13), broadband and selective excitation schemes involving iterative sequences and hyperbolic secant modulations, and the development of time domain zero-field NMR. Our long-standing interest in resolution and sensitivity led us to develop a pulsed version of nuclear quadrupole resonance (NQR) field cycling, by which it was possible to remove the orientational broadening from a powder spectrum while retaining resolved quadrupole and dipole–dipole couplings. The further development of Fourier transform zero-field spectroscopy included

various (sometimes surprising) analogs of multiple pulse techniques, spin decoupling, time reversal, spin diffusion, two-dimensional correlations, and chemical exchange. Eventually, too, we used a superconducting quantum interference device (SQUID) to detect the nuclear magnetic flux directly in zero field. Direct detection eliminated the restrictive requirements of field cycling and made it simple to obtain nitrogen-14 spectra and to study other low-frequency phenomena such as quantum tunneling in zero and low magnetic fields.

In the late 1980s, we were concerned with two aspects of the geometry of quantum mechanics and spin dynamics. On the one hand, the concepts of Berry's phase and holonomy made it possible to answer fundamental questions about quantum evolution without recourse to explicit solutions of the Schrodinger equation. Geometric concepts and gauge symmetry were sufficient to explain a number of effects that arise in systems undergoing cyclic evolution. Nuclear spins provided an ideal arena for the demonstration of geometric phases and related phenomena, and the behavior was consistent with a unification of other systems and phenomena as diverse as light, Jahn–Teller molecules, and the reorientation of falling cats.

Geometry and symmetry were also at the heart of our approach to averaging second-order anisotropic broadening effects in NMR, for example those due to quadrupolar couplings. Although MAS was very useful for the averaging of anisotropic interactions of spin-1/2 nuclei such as hydrogen, carbon-13, nitrogen-15, fluorine-19, silicon-29, and phosphorus-31, a long-standing problem in the field was what to do about the obviously important quadrupolar nuclei such as oxygen-17, sodium-23, and aluminum-27. In the presence of quadrupole couplings, the resolution was limited by second-order broadening, which is incompletely averaged by MAS.

The solution, for which we developed both the theory, with independent work by Llor and Virlet, and demonstrated the initial experiments (with the indispensable support of Berkeley's machine shop), involved motional averaging through sample spinning about two axes. Two techniques emerged—dynamic angle spinning (DAS) and double rotation (DOR)—which brought to quadrupolar nuclei the kind of resolution previously reserved for spins-1/2. During this period our laboratory often felt like a dental clinic, with the whizzing and whining sounds and rich harmonics of dynamic-angle and double rotor probes.

Whereas the geometry of MAS could be considered a dynamic implementation of cubic symmetry, an appropriate approximation to the sphere for the purpose of averaging second rank tensors, the new spinning techniques involved the next approximation to the sphere, namely icosahedral symmetry, necessary for the averaging of spherical harmonics or tensors up to fourth rank. The first experimental results were obtained for sodium-23, soon followed by high resolution spectra of boron-11, oxygen-17, aluminum-27, and rubidium-87. Applications of DAS and DOR have recently been demonstrated in a number of materials including polymers, minerals, oxides, zeolites, catalysts, and glasses, and commercial probes are now available from the instrument companies.

The most recent work in our laboratory concerns the possibility of surface NMR in samples with low surface area, a relevant interface between NMR and the realm of surface chemistry and catalysis. This poses a prominent challenge in terms of selectivity and sensitivity because of the low

concentration of surface spins in the sample. Our approach was inspired by the work of Happer and co-workers who spin-polarized xenon by means of optical pumping. We used laser-polarized xenon as a sensitive NMR spy of the surface, exploiting the sensitivity of xenon chemical shifts to chemical environment, as demonstrated by Fraissard and co-workers. The spin-polarized xenon was condensed onto the surface of a polycrystalline sample in high magnetic field where surface-specific NMR signals were observed with high signal/noise. In subsequent experiments it has been possible to transfer, by cross polarization, the high xenon spin polarization to adjacent spins, including hydrogen and carbon-13, giving rise to surface-selective and enhanced NMR spectra. With these experiments we appear to have come almost full circle—back to the original ideas of cross polarization and solid state NMR of dilute spins.

Over the last 25 years I have had the privilege of witnessing three of the major developments in NMR: magnetic resonance imaging, multidimensional spectroscopy, and high-resolution solid state NMR. Solid state NMR has progressed from the days of wide-line NMR, a curiosity for chemists, to the realm of modern high-resolution spectroscopy. These remain exciting times for solid state NMR as theory and experiments are further developed and used in many laboratories for chemistry and materials science; I look forward to the next generation of developments and surprises.

Poole, Charles P. Jr.: The Dance of the Nucleons

Charles P. Poole, Jr.

University of South Carolina, Columbia, SC, USA

My choice of magnetic resonance as a vocation, like many things in life, was fortuitous. My undergraduate training at Fordham University was in premed, and when I did not get into medical school I obtained an M.S. in physics from Fordham. My first job designing radar components and antennae at Westinghouse was entered into in June of 1952 without much forethought. This was my engineering career. While I was there I studied microwave transmission and radiation, and soon realized that I really did not know very much about electromagnetic theory. Accordingly in September 1953 I enrolled in the physics doctoral program at the University of Maryland. Soon thereafter John Davis and I were entreated by Professor Roy Anderson to join his research project to help build an electron spin resonance spectrometer, John being an expert in electronics, and myself having microwave experience. Thus my first randomly chosen job at Westinghouse determined the whole course of my future life.

Toward the end of my Maryland tenure I gave a series of lectures to my fellow graduate students, and then I wrote an extended version of the lectures called 'The Dance of the Nucleons'. The title page of the lecture notes read:

THE DANCE OF THE NUCLEONS
*Every spring the protons and electrons
assemble on the magnetic field and dance
around the quadrupole to the resonating rhythm
and modulating melodies of Larmor's lullabies.
This monograph is an exposé thereof.*

I thought that this was clever at the time, and now it is finally in print after a delay of 40 years! What I did not know was that 'The Dance of the Nucleons' was the beginning of my writing avocation. Most of the material in the lecture notes eventually found its way into chapters or books.

After obtaining my doctorate in 1958 I spent six years in the catalysis division at Gulf Research near Pittsburgh, and I learned a great deal from my association with Don O'Reilly. This was my chemistry career, studying the NMR of aluminum nuclei in silica-alumina catalysts, and various gases and reactants absorbed on the surface. While there I felt at a disadvantage because I never did figure out what an acid site on a catalyst surface was all about, but this was compensated by the fact that I understood quantum mechanics better than the chemists. At the end of my stay at Gulf I wrote, in conjunction with Don MacIver, a 97 page review article on the spectroscopy and crystallography of chromia alumina catalysis for *Advances in Catalysis*. Bill Kehl had done the crystallography. I found writing this first review a very exciting learning experience.

While at Gulf it became clear that much of the microwave knowledge that I acquired earlier at Westinghouse had never appeared in the magnetic resonance literature, and I also found

out that the copyright of the 28 volume Radiation Laboratory series of radar books had expired, which made the books part of the public domain. This caused me to start writing an ESR instrumentation book which reproduced several dozen figures and parts of many tables from the Radiation Laboratory series. It included the acknowledgment in the preface: 'I wish to express my appreciation to my wife, Kathleen, for her diligent typing of the first draft of the manuscript, and to my daughter Elizabeth whose birth during this period did not unduly delay the proceedings'.

The emphasis at Gulf was on improving catalysts and other aspects of petrochemical research. Many chemists and chemical engineers supplemented their income by applying for patents on various applications in these fields. I never submitted a patent proposal; the only patent that I obtained was the design of a high-temperature microwave cavity described in an article written for the *Review of Scientific Instruments* which had its publication held up by the legal department while a patent was applied for. Eventually I realized that my interests were more academic, and that I belonged in a university. The experience at Gulf was, nonetheless, a very worthwhile one.

I arrived at the University of South Carolina in July of 1964 for my third and last scientific job, with the emphasis on physics. My first doctoral student was Frank Griffith who already had an M.S. degree from Howard Shields of Wake Forest, and Howard himself had received his doctorate under Walter Gordy of Duke. My advisor Roy Anderson had also been a Gordy product, which made me an academic grandson of Gordy, and my first student was both a grandson, and through me a great grandson of Professor Gordy. Over the years I have helped to direct three other grandchildren of Gordy. It is indeed a small world!

While a graduate student at the University of Maryland I subscribed to the *Journal of Chemical Physics*, which was then the main source for important articles in magnetic resonance. I remember eagerly awaiting the arrival of the next issue of the journal, and often being disappointed because there was no article to read. In those days there was no trouble in reading most of the literature, and I used to send for reprints of everything that was published. Things are really different now.

Over the years I have always appreciated the chemistry and biology background that I acquired in my premed undergraduate major, because NMR and especially ESR were always on the border between chemistry and physics, and a knowledge of both helps. In contrast to many of my physics colleagues, I could always tell the difference between the aldehydes and the ketones.

A year after arriving in South Carolina my colleague Horacio Farach joined our faculty and we began an almost 30-year long collaboration which has led to the publication of several books and many research articles. I have been very fortunate to have him as a collaborator for these three decades. During the last five years it has been stimulating getting involved in the exciting new field of high-temperature superconductivity.

Biographical Sketch

Charles P. Poole, Jr. b 1927. M.S., 1952, Fordham University, Ph.D., 1958, University of Maryland. Physicist, Westinghouse Electronic

Corp., 1952–53, Gulf Research Corp., 1958–64. Associate professor of Physics, University of South Carolina, 1964–66, Professor of Physics, University of South Carolina, 1966–present. Approx. 115 publications,

including seven books, Editor, *Magnetic Resonance Review*. Research interests: solid state physics, superconductivity, magnetic resonance, Clifford algebras.

Pound, Robert V.: Early Days in NMR

Robert V. Pound

Harvard University, Cambridge, MA, USA

Academic scientific research, especially in physics, was almost completely suspended between 1940 and 1945, with the creation of specialized laboratories dedicated to the development of instruments of war. In the United States, the Radiation Laboratory at the Massachusetts Institute of Technology (MIT), was devoted primarily to microwave ‘radar’, which called heavily upon the world of academic physics. The unprecedented bringing together of scientists from widely different backgrounds, brought about lasting cross fertilization of areas of scientific interest among the participants. This, as well as the experience of large-scale funding, had many consequences on the direction of research activities after World War II.

As the war was winding down in the summer of 1945, leading to VJ Day, August 14, we, at the Radiation Laboratory at MIT, naturally began thinking again about fundamental physics and how our advancement of many electronic techniques for the radar program might be applied to more basic research. Microwave spectroscopy was an obvious possibility. An impressive measurement of the inversion spectrum of ammonia at 1.25 cm had been made way back in 1933.¹ It could be explored far more thoroughly with our new technology. A couple of other examples had been pursued for wartime purposes within our laboratory. These were the absorption spectrum of molecular oxygen in the region of 5 mm wavelength² and the absorption of water vapor, the H₂O molecule,^{3,4} in the region of 1.25 cm, at which wavelength the K-band radar had been designed to operate. Microwave spectroscopy offered especially important research possibilities to physical chemists. The frontier of physics research was largely in the study of nuclei, and it seemed less easy to transfer our novel technology into that field, except for new forms of accelerators. Most Radiation Laboratory members had for some time been making plans for their postwar careers, many returning to the institutions from which they had come. My own future had already been set in May of 1945 with my election to a three year term as a ‘Junior Fellow’ in Harvard’s Society of Fellows, from July 1, 1945. Until this honor came to me, I expected to continue my formal study in physics as a graduate student. The Society of Fellows, founded in 1933, offered to a few who were recognized early by their achievements a less formal entrance into a research career than had become the norm in Ph.D. programs.

With the end of the war, the administration of the Radiation Laboratory asked several members of the soon to be disbanded laboratory to stay until as long as June 30, 1946, to contribute to a series of books which would preserve the advances, made mainly under tight military security during the five years, for the wider engineering and scientific communities. The longevity of many of the resulting 28 volumes testifies to the worth of that enterprise. Among the members asked to stay on for that purpose was Edward M. Purcell, leader of the ‘Fundamental Development Group’, Group 41. Purcell

delayed his return to his faculty position in physics at Harvard from which he had been on leave-of-absence since January, 1941. Two others were Henry C. Torrey who headed the work of Group 53 on crystal rectifiers, and the present author who had been responsible for the design of crystal mixers, the microwave structures that employed crystal diodes and local oscillators to convert incoming microwaves to more conventional frequencies. The writing project led to my spending the first year of my membership in the Society of Fellows on a leave-of-absence.

One hot day in September, Henry Torrey and I invited Ed Purcell to join us for lunch at the small restaurant in Central Square, Cambridge, where we frequently went. On this particular occasion Purcell had been recently writing for the volume on propagation, the story of the absorption of K-band microwaves by atmospheric water vapor. He was particularly impressed that two, in this case among many, molecular states whose difference corresponded to the energy of the K-band photons, with a magnetic dipole transition connecting them, caused such absorption. Ed asked Torrey, who had done his Ph.D. thesis research in the molecular beam laboratory at Columbia under I. I. Rabi, ‘Couldn’t one detect the resonant absorption of nuclei, say protons, when placed in a magnetic field that would split the magnetic substates of the spin- $\frac{1}{2}$ protons by an amount corresponding to the energy of a radiofrequency photon?’ Applying an rf magnetic field transverse to the magnetizing field then should result in such an absorption, detectable as a drop in the impedance or of the transmission of the circuit involved in applying the rf. I recall Henry’s initial response being that he remembered there having been some talk about such a question at Columbia in the early days. He didn’t remember just why it had been thought to be unworkable. He recalls, however, feeling he had given a pessimistic response to the proposition.

One of the things that had brought the attention of the physics community, and particularly of Purcell, to the resonance techniques of the atomic and molecular beam group at Columbia was the fact that the leader of that work had been I. I. Rabi, who became a founding member of the Radiation Laboratory, and headed Division 4 under which Purcell’s Group 41 operated. We were surrounded by other veterans of the Columbia team, including the head of our rf group, Jerrold Zacharias, and, until he left for the Los Alamos project, Norman Ramsey, not to mention the continuing collaboration with the parallel Radiation Laboratory at Columbia, staffed mainly by Rabi’s former colleagues. Rabi had been awarded the Nobel Prize for Physics for 1944, at a unique special ceremony in New York.

Torrey vividly recalls⁵ thinking that evening about the question Purcell had put, and making some calculations. This changed his mind and he became excited. He went to Purcell’s office first thing next morning, apologized for his pessimism of the previous day, and described his calculations that made him think that detection should be possible. Purcell said ‘let’s do it’. I was included in the project from the beginning.

We undertook the project as a side line to our main responsibilities on the book writing project. A critical component needed for the experiment was a large magnet able to provide about 7000 G, to render protons resonant at about 30 MHz, a frequency chosen because it was the intermediate frequency of most of our radars, and we had available the least noisy preamplifiers yet developed. Purcell undertook to find such a

magnet, and failing to find one we could use at MIT, he was happy to report to us that J. Curry Street agreed to our use of the large magnet in his cosmic ray research shed at Harvard. The magnet had not been operated since 1940 because Curry Street had also joined the Radiation Laboratory at the beginning. The main yoke of the magnet had been extracted from a large generator that had been discarded by the Boston Elevated Railway (now the MBTA). It had provided the field to bend tracks in a large cloud chamber with which Street and Stevenson had determined the mass of the muon,⁶ a component of cosmic rays then on center stage. The magnet current was provided by a large dc generator in the basement of the contiguous Cruft Laboratory, and was controlled remotely by a rheostat on a wall panel in the cosmic ray shed. Our 30-MHz circuit took the form of a bridge with the sample containing protons filling a resonant cavity in one arm and with the signal transmitted through it balanced to a low level by a second arm having adjustable phase and amplitude. The bridge should suppress noise from the signal generator, should avoid overload of the amplifiers and allow observation of small fractional changes of the transmission. An output diode, added to the Hallicrafters S 36 communications receiver that followed the preamplifier, which had been a part of my apparatus for studying mixer performance, indicated the amplified residual signal and attendant noise. The choice of a cavity resonator for the sample testifies to our immersion in microwave technology for the previous four years. Most of the assembly of the apparatus took place in the evenings, except for the construction of the cavity which was machined from our drawings by Charles Rowe, a technician assigned to me at the Radiation Laboratory for several years. By later standards, the cavity and its sample volume were enormous, being an 8-cm length of shorted coaxial transmission line brought to open-ended resonance at the 10-m wavelength by a capacitive plate insulated from a lid by a thin mica sheet. With a diameter of about 12 cm, the space around the center conductor was filled with a primarily magnetic rf field when resonated at 30 MHz. When placed in the magnet with the axis of the coax parallel to the static field, the circumferential rf field was transverse. The rf was coupled in and out by small loops in that space. Most of the equipment, except for the magnet, was taken up to the Harvard laboratory from my MIT lab, but a General Radio 805B signal generator to provide the driving signal was borrowed by Purcell from the Harvard Psycho-Acoustic Laboratory of Professor S. Stevens.

As the plans went forward, Torrey and I, who shared an office for our writing enterprise, frequently discussed our 'moonlight' project. Henry realized he had assumed in his calculations that the two energy states of the protons would be in thermal equilibrium at room temperature, which would result in a very small excess population of the lower relative to the upper state. This would be a necessary condition for absorption because the rf would induce downward as well as upward transitions with equal probabilities, and no net absorption would result unless the populations were unequal. In thermal equilibrium, Boltzmann statistics at laboratory temperature and 30 MHz result in a difference of a few parts in a million. As Henry began to wonder what mechanism might bring about such an equilibrium, we raised the question with Ed Purcell. Torrey undertook to try to find some relevant ideas in the literature. He found an early paper of I. Waller⁷ on the interaction between lattice phonons and electronic spins in a paramagnetic crystal. Henry adapted the calculation to

apply to nuclei. Another paper, by Heitler and Teller,⁸ also found by Henry, actually carried out just such a scaling of Waller's mechanism to nuclei in 'diamagnetic substances' and concluded the relaxation time would be as long as 10^6 years. Heitler and Teller, however, had only evaluated the so-called first-order effect in which the interaction is directly with lattice phonons of the resonant frequency, of which there are very few compared with those at higher frequencies. Henry found that Waller's second-order process was much stronger, whereby, through the nonlinearity of the dipole-dipole interaction, phonons of all frequencies participate by scattering into phonons differing by the resonance frequency. He concluded that the 'relaxation time' from the second-order process might be as short as several hours at room temperature. Our large sample and the low rf power we would apply would allow us to observe absorption for several hours without much reducing the population difference if once relaxation to equilibrium in the field had taken place.

Several evenings were spent at the Harvard lab, clearing out five years worth of cobwebs. We brought down from an undergraduate electricity laboratory a long period galvanometer and mutual inductance with which to calibrate the field versus current and evaluate its uniformity over the radius of our cavity. Purcell designed pole caps for the magnet that were planned to make the field more uniform. These were machined in the Harvard Physics Department shop by its foreman, Carl Johnson. We expected that the dipole-dipole interaction among the concentrated protons in our planned paraffin wax sample would lead by itself to a broadening of the resonance to as much as 10 G, so, after some modifications, we felt the uniformity of the magnetic field was adequate.

Finally we were able to make a determined search for the resonance on the evening of Thursday, December 13, 1945. Ed had brought in some home canner's paraffin wax from the small grocery shop, and we melted a couple of pounds and poured the cavity full. We balanced our bridge down to receiver noise, increased the input power, and rebalanced, until we could no longer reduce the meter reading to that of pure receiver noise because of the presence of noise at 30 MHz from the GR 805B signal generator, not further reducible because the two arms of the bridge transmitted a band of frequencies differently. We watched the meter for evidence of a change in balance as we passed back and forth through the region of 73 A of magnet current that our calibration indicated for the proton resonance, given the magnetic moment as reported by the Columbia group.⁹ We scanned between about 65 and 80 A to allow for perhaps 10% error in the calibration but nothing was seen. Stare as we would at the output meter there was no movement that correlated with the changes in the magnet current. At about 4 a.m. Friday morning, somewhat discouraged, we shut down, with the agreement to try again Saturday. Ed Purcell proposed coming at about 7 a.m. and turning on the magnet. Our search would resume in the afternoon, when Henry Torrey and I would join after putting in our expected appearances at MIT. The idea was to allow the system to cook, or relax, in the field for seven or so hours, in case the relaxation time was comparable to that. The fact that the night time effort had taken a similar number of hours reduced the promise of this step.

As arranged we began the same kind of search in the afternoon of Saturday, December 15. After several hours of twisting the rheostat controlling the magnet current, watching

the output meter, and occasionally rebalancing the bridge, again nothing resembling the hoped-for resonance was seen. Late in the afternoon we decided to shut down and to think over what we might do next. All our calculations indicated that a resonance ought to double our detector meter reading, knowing that the Q value of the cavity was nearly 1000. In our minds was the idea of greatly increasing the sensitivity by going into a differential method with a modulated field and a coherent lock-in detector. During the course of shutting down, we ran the generator up to its 100 A top value and came down slowly. As we passed through 83 A, the meter kicked exactly as we had been hoping. That response proved repeatable for approach from either direction. We shut the magnet off completely and quickly brought it back; the signal was still present. We removed the cavity from the magnet and replaced it without affecting the signal. It looked as if the relaxation took place in less time than any of these maneuvers required. Our previous failures resulted from our not recognizing the degree by which the magnet iron was saturating in providing the field in so large a gap. It turned out that our calibration was only 2% optimistic, not bad for the old style flip coil, galvanometer, and mutual inductance, but it took 15% more current to gain that needed 2%. This factor allowed us to estimate a linewidth of a few gauss, when the current difference between the sides of the line were found to be about 0.5 A. We certainly should have recognized the problem sooner, because my notebook of the calibration data shows that even 102 A produced a field only a few hundred gauss greater than one of 73 A. How embarrassing it would have been if we had not accidentally discovered our error. So we were off and running with a new research tool. I was especially happy to think I had an easy way into nuclear physics, not withstanding my limited experience with the special techniques more usual in that field.

In the course of the development we heard that a project of similar intent was underway at Stanford, under Felix Bloch and W. W. Hansen. I understand that I. I. Rabi described to them our activities on a visit there in December. We also learned of the two previous unsuccessful efforts by C. J. Gorter¹⁰ and Gorter and Broer¹¹ in Amsterdam. The first of these is probably the basis of Torrey's recollections from Columbia, because Gorter visited there in 1937 and discussed his effort at some length. Incidentally, Torrey¹² has told of Rabi's giving him, early on, a very pessimistic view of the expectations of our project. We ran our experiment a couple of more times and then wrote the letter to the *Physical Review*, which is dated as received there on December 24, 1945.¹³ Bloch, Hansen, and Packard reported success soon after in a letter to the *Physical Review* that is dated January 29, 1946.¹⁴ They had begun the project on 'Nuclear Induction' considerably earlier than we but seem to have completed their design later. Bloch and Hansen had returned to full-time academic life and begun their experiment in the spring of 1945.

We were all anxious to begin a more serious pursuit of this new field, but were still committed to the writing project. Nicolaas Bloembergen came to Harvard from the Netherlands as a graduate student and undertook to work as an assistant in the spring of 1946. We quickly began developing more sophisticated instrumentation. However, before setting aside our cavity, we filled it with a mixture of mineral oil and powdered CaF_2 in which we were able to detect both the proton and the ^{19}F resonances. Henry Torrey¹⁵ and I¹⁶ each read a 10-minute paper, authored by the three of us, describing

the theory and our experiment at the annual spring meeting (the Washington meeting) of the American Physical Society, held in Cambridge in 1946 to mark the importance of the work in Cambridge in the war years. Felix Bloch came from California and gave the two papers^{17,18} his group had submitted expanded to a single half-hour talk. This provided evidence of the differences as well as the similarities of the two methods.

With Bloembergen involved, and with both Purcell and myself at last moving to Harvard in July of 1946, our project intensified. Henry Torrey, after finishing his writing assignment, accepted a position at Rutgers University, where he became the first to explore transient effects produced by rf pulses.¹⁹ At Harvard we took over a smaller magnet originally made in Switzerland in 1913 for Zeeman optical spectroscopy. It had poles of only about 6 in. diameter. We supplied the current from some large storage batteries, after finding that our small motor-generator had poor stability. We continued to use a bridge circuit, but abandoned the cavity in recognition of the evidence that relaxation times could be short enough to work with small samples contained in rf coils. The system observed derivatives of resonance lines, using a small 30-Hz modulation of the field with a lock-in amplifier, and a 30 MHz preamplifier feeding a new National Co. HRO communication receiver.

One of our first investigations was of the proton resonance in hydrogen gas, H_2 . So as to provide sufficient density of protons we constructed a cell that could contain tank hydrogen in a pressure range up to 30 atm. The complex structure of the resonance reported by the Columbia molecular beam group⁹ was known to us and, in advance, I supposed the line might be broad, reflecting the various internuclear and molecular interactions reported in the beam studies. Our first observation was at the end of the day, when we found a proton resonance, only 0.25 G wide, as narrow as any we had seen in our magnet, and consistent with the determining factor being the nonuniformity of our magnetic field. That evening when thinking about that result, I asked myself how the frequent collisions between molecules in the compressed gas would change things as compared with free molecules in a beam. I usually thought in terms of Fourier spectra of time-varying radiofrequencies, and, supposing that the collisions would switch the molecules from one substate to another, each having a differently shifted frequency, I related that effect to frequency modulation of a CW carrier at a rate rapid compared with the shifts themselves. I knew that in frequency modulation this case develops negligible intensity in sidebands, leaving the main carrier almost unaffected. Applying this model to our molecular hydrogen indicated that the interactive structure would be averaged out, a first recognition of 'pressure narrowing'. In addition to explaining the small width, the fluctuations of the interaction also provided a mechanism of spin-lattice relaxation, and measurements showed the relaxation time became proportional to pressure. The more rapid the collisions the lower the component of the fluctuations at the resonance frequency. These results were described in a letter²⁰ and thus there began the more detailed study of relaxation effects in liquids that became the widely recognized work known as BPP,²¹ which also became Nicolaas Bloembergen's Ph.D. thesis submitted to Leiden University in 1948. We realized, at last, why our initial use of paraffin wax brought us a far shorter relaxation time than Torrey's estimate

had predicted for a rigid crystal, which paraffin clearly was not.

Another study performed in those early days was the measurement of the linewidth of the ^{19}F resonance in a single crystal of calcium fluoride, as a function of its orientation in the magnetic field,²² confirming the quantitative analysis of our colleague, J. H. Van Vleck for the 'second moment' of the lineshape function,²³ as produced by the dipole-dipole interactions in the rigid lattice. A second graduate student, George Pake, soon undertook a research project with E. M. Purcell, and he made lineshape studies in rigid crystals. His thesis was based on his study of the lineshape of the proton resonance of the water of crystallization in single crystals of gypsum,²⁴ $\text{Ca}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, which marked the start of a widespread application of NMR to problems in crystal structure. I still liked to think that NMR was a way into nuclear physics, and finding resonances for nuclei with relatively uncertain moment values seemed to be such a route. Bloembergen and I spent some unrewarding hours sweeping the field by sliding our crude current control resistance while staring at the fluctuations of our output meter on the lock-in amplifier, trying to detect the resonance of bromine isotopes, among others.

I. I. Rabi paid a visit and spoke about his Columbia group's work with molecular beams at our departmental colloquium in February, 1947. He included the description of effects from nuclear electric quadrupole moments in molecules and described resonances in low magnetic fields in which the frequencies were entirely determined by the nuclear quadrupole splittings. Rabi emphasized that extraction from the spectra of a quantity for the nuclear quadrupole moment was hard, because the electronic field gradient to which the splitting was proportional was too difficult to evaluate reliably. It occurred to me that a similar effect should exist in ionic crystals of lower than cubic symmetry, and I supposed that there, since ions are generally of closed shell, noble gas structure, the field gradient might be simply calculable from the structure parameters, assuming each ion to act as a point charge. To pursue this idea, I needed a spectrometer that could search in frequency, and our bridges or the crossed-coil device of the Stanford group seemed too difficult to convert to frequency scanning, requiring many tracking controls. This was the driving force behind my development of the regenerative, or controlled marginally oscillating, detector,²⁵ often spoken of as the Pound Box, with which I initially planned to try to find some magnetic resonant absorption at frequencies determined by quadrupole splitting without a magnetic field. My initially preferred candidate was hexagonal HgS , cinnabar, which I naively supposed to be ionic. With the spectroscopists' value for the quadrupole moment, and a simple estimate of the crystalline field gradient, I hoped to predict a frequency. However I soon found the slow convergence of the lattice sum for the field gradient made the evaluation difficult. I realized that this search was not likely to succeed, and I went back to using a magnet and applied my simple spectrometer to determine a few g -factors, as a contribution to nuclear physics. These included the two bromine isotopes,²⁶ the two copper isotopes,²⁷ the two gallium isotopes, and phosphorus ^{31}P .²⁸ The bromine isotopes are of almost identical natural abundance, but I was able to assign the nuclear magnetic resonances to the individual isotopes by using the fact that the relaxation in the liquid

state was caused by the fluctuating quadrupole interaction, the broader line thus going with the isotope of larger quadrupole interaction, as already known from microwave spectra. Chemists studying rotational spectra of molecules with microwaves were reporting nuclear spins and quadrupole interactions, and I supposed that molecular interactions would be similar for such molecules in the solid state. However, demonstrating that didn't seem to me as rewarding as studying ionic crystals, because the problem of evaluating the field gradient in molecular crystals would be even more difficult than in the diatomic molecules described by Rabi.

The scanning spectrometer was successfully applied to the detection of electric quadrupole splittings in crystals with light nuclei such as ^7Li , ^{27}Al , and ^{23}Na . In these cases the quadrupole interaction, being smaller than the magnetic one even in my small magnet of only 3 kG, was treated as a perturbation of the magnetic structure. In the case of the aluminum resonance in corundum, Al_2O_3 , I carried the perturbation calculation to the third order to give an adequate fit. One of the more novel experiments described in the extensive paper on these efforts²⁹ was the first example of double resonance. I applied saturating rf to one of the three well-resolved quadrupole split lines of the spin- $\frac{3}{2}$ ^{23}Na in a single crystal of NaNO_3 and recorded the resulting change in strength of the other lines. The results agreed with a detailed balance calculation that used the matrix elements of the quadrupole interaction in the relaxation assuming a modified Waller mechanism. Relaxation by magnetic interactions via impurities, as seemed to be the case for spin- $\frac{1}{2}$ nuclei, would not fit. My simplistic ideas on quadrupole interactions in ionic crystals were rather dashed when Rudolph Sternheimer showed³⁰ that distortions of the electron shells of the atoms and ions had enormous influences. He derived shielding and antishielding factors amounting to many hundreds for some atoms. Little hope remained for important data for nuclear physics from the quadrupole interactions in crystals.

Although I had not initially been attracted to the possibility of studying the interactions in molecular crystals containing, for example, bound halogens for which interaction strengths were already reported from gaseous molecular spectroscopy, I realized in 1949 that in some cases the interactions could be large compared with thermal energies at low temperature and would thus result in nuclear alignment,³¹ which had possible interest for nuclear physics. Thus I began again an effort to detect the so-called 'pure quadrupole resonance', this time of ^{127}I in molecular solid iodine, which I believed would be easily found, although in the then electronically awkward frequency region of 1500 MHz. Before I was successful, Dehmelt and Kruger reported detecting pure quadrupole resonance in solids for the example of chlorinated ethylene³² in the more conventional frequency region of 30 MHz.

Among several rather pure crystals I acquired from the Harshaw Chemical Company was one of LiF . I was surprised to discover that the relaxation time of the ^7Li at room temperature was as long as 5 min, varying somewhat with its orientation in the field. By probing the resonance periodically with the oscillating detector I was able to display on the chart recorder the build up of the magnetization after initially inserting the crystal cemented to the end of a wooden dowel. Immediately came to mind the question that had arisen in our first experiment with paraffin; once magnetized, what happens if the crystal is removed and then replaced in the

field? By doing so, I found that even in the Earth's field the crystal retained its reduced entropy, apparently becoming adiabatically demagnetized to a low absolute spin temperature and recovering its magnetization at high field if not kept out too long. In fact, by measuring the loss as a function of the time out of the magnet, I concluded that the relaxation time in zero field (actually the Earth's field) was about 15 s. Trials showed that the remagnetization was independent of any gyrations and rotations one made while out of the magnet. I published a letter describing this observation,³³ and soon after was joined by E. M. Purcell in an effort to trick the spins into some other condition while in the weak field. At first there was the thought that, since the spins could only reorient at a rate slower than their rate of precession in the weak field, a change of direction of such a field faster than that rate could not be followed. I was sure, however, that in the demagnetized state the field at each spin is the dipolar field of the neighbors and the macroscopic polarization is lost. A field large enough to retain the polarization would be needed and any quick transit through weaker fields should be fast compared with a 'spin-spin relaxation time' closely related to the linewidth caused by the dipole-dipole interaction.

We built a device using a small permanent magnet providing about 100 G, and a small solenoid in that field through which we could discharge a capacitor. The current rose and reversed the field in less than a microsecond but a series resistance slowed the return to the field of the small magnet to take more than a millisecond. Moving the magnetized crystal from the resonance magnet, placing it in the coil near the small magnet producing the discharge and returning the crystal to the NMR magnet, all in a few seconds, resulted in an inverted NMR signal. Such a signal corresponded to emission rather than absorption. It decayed through zero and back up as an absorption, with the same 5-min time constant already noted. We emphasized that the crystal suffered demagnetization to essentially zero field not only in transferring to the flipping gadget but again on the return when it was in this unnatural state. We termed its condition a 'spin system at a negative temperature'. The concept can be shown to be well based in thermodynamics and statistical mechanics and has entered many textbooks. Simpler inversions are easily produced in the liquid state, for example by fast passage, but there is no mechanism there producing internal equilibrium at a rate faster than the spin-lattice relaxation. In the rigid lattice the spin-spin interaction causing mutual flip-flops among like nuclei maintains a statistically probable state in the isolated spin system, even when fully demagnetized and inverted. The inversion is a way to put more energy into the spin system than corresponds to infinite temperature, so higher levels must become more populated than the lower ones. There is no way to obtain this condition from a normal thermal state and it can only be produced in a system with a bounded number of energy levels, like the spins. Our letter³⁴ stirred up controversy among thermodynamicists, but the concept slowly became generally accepted. Unfortunately the term 'negative temperature' has frequently been applied to such inversions as are invoked to produce lasers, but there no internal equilibrium exists. In quite another way we did influence the development of lasers and masers. Our description of the role of stimulated emission has been credited by C. H. Townes with playing a role in his conception of the first maser.³⁵

These are some of my recollections of my involvements in the first five years of NMR. My effort to emphasize the nuclear physics aspect of the subject found little reward as results instead led to a wide range of applications in condensed matter physics, followed by chemistry, then biology, and perhaps most impressively of all, to medicine. I am grateful to my friends and collaborators, E. M. Purcell, H. C. Torrey, and, N. Bloembergen for helpful comments on this manuscript at several stages.

Biographical Sketch

Robert V. Pound. *b* 1919. B.A., 1941, Physics, Univ. of Buffalo, M.A. (Hon.), 1951, Harvard, D.Sc., 1994, SUNY at Buffalo. MIT Radiation Laboratory, 1942–46, collaborator with E. M. Purcell and H. C. Torrey in first successful detection of NMR in condensed matter, December, 1945. First double resonance experiment, study of nuclear

quadrupole interactions, oscillating detector spectrometers. With E. M. Purcell, introduced concept of negative spin temperature. With A. Abragam, explained effect of nuclear quadrupole interactions on directional correlations of successive nuclear radiations. Developed nuclear γ -ray resonance of ^{57}Fe to prove effect of gravity on photons. Mallinckrodt Professor of Physics, Emeritus, Harvard University since 1989.

Powles, Jack: Reminiscences of the Early Days of NMR

Jack Powles

University of Kent, Canterbury, UK

This is a personal account of my memories of NMR from 1952. I am no historian and my memory for facts and dates and people may not be very accurate 40 years on. If there are errors of commission or omission, especially when I name individuals and their doings, I must ask the kind indulgence of those people and the readers of this volume.

From 1945 to 1951 I worked on dielectric relaxation in liquids and solids with Willis Jackson in Manchester and Imperial College, London, with Edmond Bauer and Michel Magat in Paris, with Herbert Frohlich in Liverpool and with Charlie Smyth in Princeton. This gave me a lifelong interest in *relaxation* processes in a great variety of materials. I was a bit tired of dielectrics by 1951 and in the Princeton library I came across, by accident, the BPP paper¹ and Bloch's paper² and it was immediately clear to me that this novel method of spectroscopy was a new and powerful method of studying molecular motion in Nature and rate in condensed matter. Indeed it is much more powerful than dielectric spectroscopy since no electric dipole is necessary, just some suitable nuclei. Among these, for one, the most attractive to me was the proton since I had a longstanding interest in ice and water, the solid hydrogen halides, and methyl groups in particular. So, being quite good on electronic circuitry, statistical mechanics, and quantum mechanics, I thought I could change techniques quite easily. The opportunity presented itself and I became a research fellow with Herb Gutowsky in the fall of 1952 in Urbana, IL.

There was, in Herb's lab, a broadline spectrometer in working order. I churned out a mass of results^{3–5} on samples of tetrasubstituted methanes (CCl_4 , CCH_3Cl_3 , etc. and mixtures thereof) of which I had studied the dielectric relaxation in Princeton and which Charlie Smyth kindly lent me. These were very nice things to learn on since they had a variety of line-narrowing processes, methyl reorientation, molecular partial reorientation, molecular isotropic reorientation, and molecular translation. The phase diagrams were quite complicated⁴ and were materially quantified and explored by the sudden linewidth changes at phase transitions—perhaps the first instance of this use of NMR. This added to the very few studies of NMR in organic solids up to that time. We also found an effect novel to NMR at the time. It was familiar to me from earlier dielectric work.^{6–8} I refer to the reorientation of methyl groups about the C_3 axis by a tunneling mechanism.⁵ The apparent activation barriers were far too low, about 2 kcal mol^{-1} instead of 6 kcal mol^{-1} , and this was very neatly explained by a rather crude but adequate analysis of the reorientation by tunneling. Unfortunately, it could not be unequivocally established by deuteration as it had in HBr/DBr ,^{7,8} but it was surely correct. Of course tunneling, especially of methyl groups, is now a big industry, especially the work of Stan Clough in Nottingham, and many weird and

wonderful offences against the pristine beauty of our nice simple experiment have been committed.

It should be mentioned that at this time in the laboratory next door, Herb and his students, Len Meyer and Dave McCall, were establishing the values of the proton chemical shifts for vast numbers of organic liquids scrounged from throughout the Noyes Laboratory. It is well known this is the basic information⁹ and the beginning of the major industry of chemical analysis by nuclear magnetic resonance spectroscopy. Being a physicist I thought it was the most boring series of experiments I had ever heard of and I took little notice! This is an example of the commercial and technical application of NMR being excruciatingly dull as far as science is concerned, but the chemists went crazy over it. One advantage was that people soon started making decent magnets commercially and a lot of good science was done on these.

One great advantage of being in Urbana at that time was that in physics there was Charlie Slichter and his students, Myer Bloom and Don Holcomb. Norberg had just gone to St. Louis and Erwin Hahn to Stanford. This group was much oriented to pulsed NMR¹⁰ and it seemed to me that the future lay in that direction, especially for the study of molecular motion. However, I was not able to do that for some time, it was too novel for the people with the money and power to understand. The chemists were particularly skeptical I remember—'What is a Fourier transform?'

On returning to England, to Newcastle, in 1954, for a year, I managed to get a half-decent magnet and a chart recorder and built a broadline spectrometer which worked. I was just wondering what to do with it when I was visited by a party from ICI Plastics of Welwyn Garden City who were intrigued by this new technique. We were on the same wavelength because they were very knowledgeable about the dielectric relaxation in polymers and in fact knew my widely-quoted work on dielectric relaxation in polythene.¹¹ They were mainly concerned with mechanical relaxation. Most polymers are sold for their mechanical properties to this day. I was rash enough to claim to be able to predict mechanical relaxation from NMR, especially if I could do T_1 as well as T_2 measurements. In fact, to everyone's astonishment, including mine, I did actually manage to do this and so we were very early into NMR in polymers closely followed by Bill Slichter and Dave McCall at Bell Laboratories. This lasted some 15 years until ICI had a financial crisis and sacked all its most useful, and cheapest employees, their consultants, a commercial idiocy about the use of science in British industry which keeps us poor to this day. It was astonishing how quickly this field developed as witnessed by a review article I wrote in 1960,¹² from which one can see that NMR in polymers was already a major study by that time.

However, I moved to Queen Mary College, London in 1955, and at last was able to get support to do pulsed NMR. I had some excellent students to help me in this. John Luszczynski observed what must have been the first spin echoes to be seen outside the US.¹³ Peter Mansfield built an even better pulse apparatus¹⁴ and did a series of very nice measurements of T_1 and Bloch decays in all sorts of materials. Doug Cutler observed the first electron spin echo, in sodium/ammonia.¹⁵ I think we were the first to use rf phase shifted pulse trains, 90_0 , τ , 90_{90} , etc.,^{16,17} which was the first attempt to remove the dipolar interaction in solids by pulse trains, which we

called ‘solid echoes’. These are I believe discussed in more detail by my former student John Strange elsewhere in this volume (*Strange, John H.: Echoes of the Past*). Similar work was being done, as we discovered later, by John Waugh at MIT quite independently. This developed into the elaborate and complex pulse trains which were developed subsequently by John Waugh and by Peter Mansfield when he went to Nottingham. It was amusing to be yet again measuring the solid hydrogen and deuterium halides, in 1968 this time by NMR.¹⁸ We systematically showed that anything that could be done by steady-state spectroscopy could be done, usually faster and more easily, by spin echoes, for example the measurement of J coupling.¹⁹

I thought this was getting just too technical and elaborate for me, what with the rotating frame and multiple quantum transitions and what not. I felt that by 1970 or so NMR was getting too ‘mature’ and I looked around for something more exciting and with fewer able competitors! This was shortly before magic angle spinning and magnetic resonance imaging began really to get going! But I do not regret it; I am primarily interested in molecular motion and relaxation processes in condensed matter and one technique like NMR, powerful though it may be, is not enough. Indeed a narrow view using NMR only is often quite misleading.²⁰ On the other hand, I find one gets little credit for being knowledgeable in several fields. My advice to young people is, do not be interdisciplinary, be narrowminded but collaborate.

So I moved over to neutron scattering in 1971²¹ and to computer simulation of liquids, my principal interest ever since, in 1973.²² I look with wonder and awe at the remarkable things which are now done with NMR—but without any regrets, it was fun while it lasted!

Jack G. Powles. b 1924. B.Sc., 1945, Ph.D., 1948, Electrical Engineering, Manchester University, UK, D. ès Sc., 1951, Sciences Physiques, University of Paris. Introduced to NMR in 1953 by Herb Gutowsky and Charlie Slichter. Foundation Professor of Physics University of Kent, UK, 1964–1991. Now Emeritus but still active! More than 230 published papers, all worth reading. Main interest, computer simulation of liquids.

Proctor, Warren G.: When You and I Were Young, Magnet

Warren G. Proctor

Humlebaek, Denmark

I began my graduate studies early in January of 1946, the beginning of the winter trimester at Stanford University. Stanford, in 1946, was indeed the 'farm', a large sandstone quad and a few other buildings set amid grassy fields and trees. The Physics Department occupied one corner of the quad—I suppose the departments might have been arranged alphabetically because psychology was next to physics. There were about 15 beginning graduate students in physics. The faculty at that time was also quite small, but it is important to mention that Professors Felix Bloch and W. W. Hansen were among the half-dozen faculty members.

A memorable thing, related to the Physics Department colloquia held on Thursday afternoons, happened to me almost immediately. The first talk I heard was given by Professor Bloch who described the success of Professor Hansen, a graduate student named Martin Packard, and himself in observing nuclear magnetic resonance, which at that time he called nuclear induction. I must admit that I failed to grasp the significance of the discovery. I was fascinated by the instruments which had been carried up from the Physics Department basement to the lecture platform, where young Packard, while Professor Bloch was speaking, unsuccessfully attempted for an hour to show us a proton signal. I thought that all colloquia would be similar—each professor in turn describing to us the various interesting things he had observed in recent weeks.

Professor Bloch's ideas on magnetic resonance (he told me later) had been quietly worked out at home during the war years that he had spent at Harvard University. This made it possible to perform the experiment within a few months after his return to Stanford at the end of the war. The brilliance of his concept was clouded by only one thing: he had neglected to anticipate the narrowing of the lines in liquids due to their thermal motions, as explained by Bloembergen, Purcell, and Pound in their classic paper a year or so later. Until word of line narrowing reached Stanford, each time that a nuclear magnetic resonance signal was seen, the broad line that had been observed was always thought to have been its natural linewidth, in keeping with Bloch's simple dipole-dipole broadening mechanism. It was, in truth, due to the inhomogeneities of the magnets available in the Stanford Physics Department in those years.

For me, there was a period of about two years totally devoted to class work. One certainly heard about NMR in the department, and I remember two further colloquia which exposed me to the subject. One was given by Packard himself, an enjoyable talk from an experimentalist's point of view. Another talk was given somewhat later by Professor Bloch who had, with Packard, worked for several months at Los Alamos to measure the magnetic moment of tritium from a sample of the compressed gas. The emphasis at this time was

the measurement of nuclear magnetic moments, and no doubt it was hoped that a precise measurement of many moments would provide some key to the understanding of nuclear structure.

The way I began working with NMR was the following. I was earning a little money correcting homework and examination papers for Professor Hansen, who was giving a course on microwaves. Professor Hansen came into the room where I was working one day and said that one of his graduate students had become much more interested in one of his new ideas—a linear electron accelerator—than he was in NMR. Hansen then asked me if I would be willing to take on the work that Richard Post would like to drop. Post had been given the thesis problem of building an automatic instrument that was to search for the magnetic resonances of all reasonably accessible stable isotopes. At this point I should say that my early wanderings in the physics basement taught me one thing: do NOT, I repeatedly had told myself, consider for a moment any research problem where vacuum was involved. This condition satisfied and having liked what I heard about nuclear induction, I accepted at once.

So I took over a very polished and complex apparatus that included a method of phase detection able to detect the U and V modes without having to tune for them at the probe. The reason for this was that the probe was simply inaccessible. The magnet had been built by a weird-looking fellow named Russell Varian. At one point I was bold enough to ask Professor Hansen why this fellow, who seemed to do little else but wander around, was hired by the Physics Department. I still remember Hansen's reply: 'You don't think he is doing anything, my boy, but the wheels are going around, the wheels are going around.' It was this thinker who constructed the magnet after a general design by Bitter. He realized that some magnetic moments would be very small, hence the highest possible fields would be necessary. Russell Varian consequently built a magnet which was totally enclosed, that is to say the magnet had complete cylindrical symmetry about a line running through the center of its poles. When looking at it one was simply faced by a large cylinder of steel, and there was no apparent access to the gap. Instead of opening a window at one side, as one would presumably do today, Varian felt it to be more sensible to have long holes drilled through the pole pieces and the pole caps for access into the gap since, NMR lines being broad, homogeneity was not a problem, but field strength was!

Only once during this time when the idea of motional narrowing reached us did I hear Felix Bloch express himself about it. I do not remember his words, some of them being possibly unprintable, but he was clearly furious with himself for not having thought of it.

Professor Bloch insisted for a number of years that the phenomenon be known as nuclear induction. I remember wondering about how this was all going to turn out until one day, in the basement, he called us all together. Who was there? Packard, Arnold, Dharmatti, Yu, Levinthal, Rogers, Jeffries? 'I have had a meeting with Purcell', he explained. 'It is important to be consistent with the nomenclature generally used in physics. It will be known as nuclear magnetic resonance', he concluded.

However, it was with this instrument that my practical introduction to NMR began. Moving to a large nearby magnet, it did not take me long to learn that the remaining part of

this magnificent apparatus was, for reasons I have forgotten, equally unsuited for the job that it was built for. During this time of construction and experimentation, problems of a practical type frequently arose. Who should one consult but one's thesis adviser? An electronic problem had arisen one day that baffled even this experienced seat-of-the-pants radio amateur, so I turned with my question to Professor Bloch. He invited me to the blackboard where I was horrified to see him beginning to write down Maxwell's equations! But, in the end, with a spectrometer consisting of a simple tracking transmitter and receiver, and a good magnet, I was ready to work and needed an easy target.

Poss had just observed ^{205}Tl but had failed to see the weaker resonance from ^{203}Tl . I decided to give it a try and was successful. I blush to remember my ridiculous pride as I sat in the audience nervously waiting to have my paper called at the Stanford Winter Meeting of the American Physical Society: my first professional appearance, describing to a bored audience the exciting news of a more precise value of the magnetic moment of thallium-203.

In the fall of 1949 Professor Bloch told me that he had invited Dr. F. C. Yu to work with me. Dr. Yu, he explained, wanted to learn about NMR, having completed his dissertation in another field at Ohio State. The following year proved scientifically exciting and personally rewarding, for Fu Chun Yu has remained a life-long friend. Of the many impressions I have of him at that time, I shall recall only one here: the basement NMR gang had driven for lunch to a Chinese restaurant located in a rickety building near the railway tracks in Mountain View. I had not been there before with Fu Chun and was surprised when he led us all through the dining room, through the kitchen, and into a small room with a large table in the back. A young man with pad and pencil arrived. Fu Chun took these and wrote some oriental symbols on the pad. 'What did you order for us, Fu Chun?' I asked. 'All we can eat for one dollar apiece,' he said. We worked together for one year during which time we found 18 new resonances and probably made the first observations of the chemical shift and spin-spin coupling.

The observation of the chemical shift was a classical case of an accidental discovery. The magnetic moment of ^{14}N was known fairly well but we wished to measure its magnetic moment more precisely. I remember going into the little Chemistry stockroom and searching for a compound which would give us the strongest possible resonance. I fell upon the bottle marked NH_4NO_3 because it was obviously very soluble in water and furthermore had two nitrogens per molecule. Downstairs we made up a concentrated solution and set it in the instrument. Fu Chun and I were facing each other, leaning on the magnet, anticipating the resonance as the small clock motor slowly changed the frequency of the spectrometer. As expected, a lovely resonance appeared on the recorder tape and, as we watched it, we were astounded to see the first resonance followed by a second one of equal amplitude. We repeated this measurement several times to make sure that there was no possible instrumental error and took the traces upstairs to Professor Bloch's office. He became very excited and we discussed possible reasons for the double resonance. There could be two reasons—one far more interesting than the other, namely that there were stable nuclear isomers with slightly different properties! We were hoping that we had made such a discovery. The second reason could be, of course,

that it was some nasty chemical phenomenon, most probably a difference in the diamagnetic shielding due to different electron densities around the nitrogen nucleus. It was at this conference that Professor Bloch explained to us for the first time the next perturbation, the Van Vleck paramagnetism, which we decided later must contribute. A few days later he told us that he had arranged for Dr. Emilio Segre of the University of California to send us a sample of liquid ammonia, enriched in ^{15}N , because, as we later wrote about the presumed 'chemical effects': 'It seemed particularly important to us to verify that they were indeed of a chemical origin and not connected with questions of nuclear structure.'

I can still almost feel the agony of waiting several weeks for the enriched sample—such a spectacular observation could easily be observed and reported by someone else! Now here is where fact and fancy separate themselves. The 40 some years since that time have romanticized these events. Had I not taken the trouble to reread our publications, I would have written here that we agonizingly waited for the enriched sample before publishing, in order to be absolutely sure that the two resonances were of molecular origin. Consequently our letter was delayed . . . to be published in an issue which also contained Dickenson's description of the chemical shifts he had observed for ^{19}F . Now, years later, looking up these old papers in the cellars of a modern university library, where ancient publications are stored, I have been shocked to learn that our first announcement of the chemical shift did not mention any measurements at all on ^{15}N . We did, indeed, rush into print without being absolutely sure that nuclear isomers were not involved, and my memory of the agony of waiting for the ^{15}N sample from Berkeley has been shown to be the stuff of good drama.

Dr Yu and I were also fortunate to discover, as far as I know, the first example of the spin-spin interaction: the very pretty multiplet observed for the resonance of ^{121}Sb in the ion SbF_6^- . This time we were astounded to see a multiplet of five lines. (Weaver later showed that there were seven.) This, of course, was manifestly impossible unless the SbF_6^- ions were impeded in their rotation. I remember sitting down and working out the pattern of magnetic fields one would expect to find at the antimony nucleus if one had a random but static distribution of the ions, taking into account the complexities of the spin distribution. The incredible thing was that this calculation gave a fairly satisfactory description of the multiplet we had observed. I remember being fairly happy with the explanation, but I remember equally well being unable to convince more experienced physicists of it. Indeed, I offered this explanation at the departmental colloquium at the University of California at Berkeley about this time and was greeted with loud shouts more characteristic of the British parliament than of a physics colloquium. This did not, however, prevent Dr. Yu and myself from describing this unusual interpretation in print. We were supported in our views when Prof. E. R. Andrew later suggested a mechanism that could explain the impeded motion: long chains of alternating hydrogens and SbF_6^- ions. However, it was about a year after this that Slichter and Hahn at Illinois noticed these interactions in hydrogen spectra and proposed the now well-known scalar interaction.

These days of discovery were exciting. What new nuclear or chemical mysteries were to be revealed with the next

nucleus? Sample inserted, field and frequency set for an all-night search, I bicycled through the early morning sunshine of Palo Alto to the Physics corner basement to examine eagerly the large heap of chart paper lying on the floor, sometimes on a very wet floor because the magnet had leaked overnight. A weak resonance could best be seen by pulling the paper straight and sighting along it from one end, suspicious areas to be reexamined during the course of the morning: a new resonance...a triumphant cup of coffee with Fu Chun ... happy discussions with Bloch ... the newer students Harry Weaver and Weston Anderson standing nearby.

But these years soon came to an end. Erwin Hahn and I, at an afternoon departmental coffee, in the late summer of 1952, he to leave for IBM and I to the University of Washington, wondered what we were to do next. We had no ideas. NMR is dead, we concluded.

How wrong we were! At the University of Washington I decided to start working on nuclear quadrupole resonance without having a clear idea where it might lead. As a young instructor I was given a roomy corner laboratory on the ground floor of the physics building, completely empty, and a miserable departmental allowance for purchases. Nuclear quadrupole resonance was built for a situation like this—no magnet necessary, elementary electronics, and the Mineralogy Department for samples. With several students the quadrupole resonances of boron and aluminum were studied in the hope of contributing to the partially known structures of the minerals involved. I should point out that NQR is really NMR—magnetic dipole transitions between energy states given, of course, by the interaction of the quadrupole moment with the internal crystalline field gradients.

I wish it were possible for me now to recall how the idea came, but come it did: how truly to make quadrupole transitions between quadrupolar energy states, pure quadrupole resonance indeed. It was a simple idea—modulate the

quadrupolar interaction with ultrasonic waves at the transition frequency in a direction such that off-diagonal matrix elements were involved. Walter Tantilla had at that time asked about a thesis problem and he got this one. We wanted only to demonstrate that transitions took place and so took the easy way out: we would monitor the population differences by NQR with and without sonic waves. We chose to use NaClO_3 because single crystals could be easily grown and the resonant frequency of chlorine was conveniently high, around 30 MHz. I shall never forget the letters we received after our letter was published. One from Bloch, congratulating us on 'catching such a pretty little fish'. And two further letters, one from Al'tschuler and one from Kastler, both kindly pointing out that they had proposed such an experiment in earlier papers. Other experimenters made the short life of nuclear acoustic absorption, as the field was called, into something useful. For example, by monitoring the resonant absorption on the ultrasonic transducer itself one was able to study the otherwise inaccessible quadrupolar interactions in the interior of metallic crystals. Perhaps the future will find a new need for NAA—who knows?

Professor Bloch has told you how one can detect the precession of the magnetic nuclei in a drop of water. Commonplace as such experiments have become in our laboratories, I have not yet lost a feeling of wonder, and of delight, that this delicate motion should reside in all the ordinary things around us, revealing itself only to him who looks for it. I remember, in the winter of our first experiments, just seven years ago, looking on snow with new eyes. There the snow lay around my doorstep—great heaps of protons quietly precessing in the Earth's magnetic field. To see the world for a moment as something rich and strange is the private reward of many a discovery. But I'm afraid it has little bearing on the sober question we must, as physicists, ask ourselves: what can we learn from all this about the structure of matter? It is my privilege to tell you now of some of the things that can be learned.

Let us begin with the most direct application of nuclear induction methods, the measurement of nuclear magnetic moments. The basis for this is the resonance condition

$$f = \frac{\mu H_0}{Ih} \quad (1)$$

in which f is the frequency of precession of the axis of nuclear spin in a magnetic field of strength H_0 , and μ is the magnetic moment of the nucleus. The number I is the nuclear spin quantum number, an integer or half-integer, and h is Planck's constant. Now H_0 , except for a certain slight correction, is simply the field of the magnet in which the substance has been put, and it can be measured. The frequency of precession, once it is detected, is easily measured with high accuracy, and thus one can determine the quantity μ/Ih . However, for practical reasons, it is hard to measure the strength of a magnetic field very precisely. This difficulty is avoided if one is content to measure the *ratio* of the magnetic moments for two different nuclear species. We could, for example, compare the precession frequencies f_H and f_D for protons and deuterons exposed to the *same* magnetic field H_0 . A mixture of light and heavy water, H_2O and D_2O , might serve as our sample. Then f_D/f_H is the ratio of the magnetic moment of the deuteron to that of the proton, apart from the simple factor I_D/I_H , which is the ratio of the spins, in this case 2. In this way the magnetic moments of many different nuclei have been measured, relative to the moment of the proton, with great precision.

To show what accuracy can be achieved, let me describe one example, a very recent experiment by F. T. Wimett in the laboratory of Professor Bitter of the Massachusetts Institute of Technology. The ratio of the deuteron moment to the proton moment had been carefully determined before by Anderson

and Smaller at Chicago, and by K. Siegbahn and Lindström here at the Nobel Institute. Wimett has now refined this measurement still further using as his sample the gas HD . This substance has a certain advantage: the two different nuclei are not only in the same vessel, but in the same molecule, so there is no doubt that the magnetic field at each is the same. Figure 1 shows simultaneous traces of the proton resonance and the deuteron resonance in a field of about 15 000 G. You will notice at once that the resonances are not simple. The proton resonance is a triplet line, almost fully resolved, while the deuteron resonance is a cleanly resolved doublet. This has an interesting explanation, to which I shall return near the end of my lecture, but it has no direct bearing on this experiment except to emphasize the extraordinary resolution. The separation of the deuteron doublet is only 0.07 G, 1 part in 200 000 of the applied field. By carefully lining up the central proton peak with each deuteron peak, in turn, a measurement reliable to about 1 part in 10 million can be made. The determination of the exact frequency ratio is accomplished by an elaborate scheme of harmonic multiplication. Wimett's result, which he kindly gave to me just a few days before I left Cambridge, is

$$\frac{\mu(D)}{\mu(H)} = 0.307\,012\,189 \pm 0.000\,000\,030. \quad (2)$$

The results of four earlier experiments of this sort are listed in Table 1. Of course the neutron experiment is a very special one, and Professor Bloch has already described his elegant method for detecting the neutron precession frequency. The other values were obtained by various investigators¹ in the way I have just indicated. These numbers provide a very stringent test of any theory of nuclear structure. A wholly satisfactory theory ought to be able to predict them. As you know, we are very far from having such a theory now. But even so, the high accuracy is not all wasted. The moment of the deuteron is not *quite* equal to the sum of the moments of its separate parts, the neutron and proton. Thanks to the extreme precision of the experimental values, this small but significant discrepancy is itself fixed quite accurately.

As we leave the simplest nuclei and proceed through the Periodic Table, the situation changes a little. The experimental precision is just as high, but one must apply to the measured frequency ratios a small correction to take account of

Figure 1 Simultaneous display of deuteron and proton resonances in HD . The proton trace is inverted. (T. F. Wimett, Massachusetts Institute of Technology)

Table 1 Magnetic Moments of the Neutron (n), Deuteron (^2H), Triton (^3H), and ^3He , Relative to the Moment of the Proton (^1H)

$\frac{\mu(n)}{\mu(^1\text{H})} = -0.685\,001$ ± 3	$\frac{\mu(^2\text{H})}{\mu(^1\text{H})} = 0.307\,012\,25$ ± 10
$\frac{\mu(^3\text{H})}{\mu(^1\text{H})} = 1.066\,636$ ± 10	$\frac{\mu(^3\text{He})}{\mu(^1\text{H})} = -0.761\,815\,0$ ± 12

the magnetic shielding effect of the atomic electrons. This correction increases rapidly with atomic number. Until better atomic wavefunctions are available, it cannot be calculated reliably enough to support the six figure accuracy of the resonance measurement. There is one important exception. For two isotopes of the same element, the correction cancels out. Accurate moment ratios for isotopic pairs are of considerable interest, especially if the hyperfine structure interval for the two isotopes can be determined. A. Bohr and Weisskopf² have shown that such a comparison can reveal something about the internal structure of the nucleus.

Perhaps the greatest present need, through most of the Periodic Table, is for spin values and only moderately precise moment values, to help test the promising shell theories of nuclear structure. Nuclear induction methods will surely continue to contribute to this task. Spin determinations in particular, which depend on careful intensity measurements, are likely to receive more attention.

The experimental physicist often needs to measure the intensity of a magnetic field. Until recently a precise magnetic field measurement has been a formidable undertaking, but it is such no longer. At the National Bureau of Standards in Washington, Hipple and his collaborators³ have measured the proton precession frequency and, at the same time, have measured in absolute units the intensity of their magnetic field. All the resources of the Bureau were brought to bear on the latter measurement, and an accuracy of 1 part in 40 000 was achieved. Knowing their result, an experimenter anywhere in the world can determine absolute magnetic intensities to the same precision, using equipment no more elaborate than an ordinary radio receiver. He need only determine the proton precession frequency in the field in question. Few physical quantities are as easy to measure accurately as a radiofrequency, thanks to modern electronic techniques and the availability, in most countries, of standard-frequency broadcasts.

Already a number of experiments have been performed in which the nuclear resonance has served as a standard of reference. Certain ones are of special interest because they have improved our knowledge of the fundamental atomic constants. In each of these experiments two *different* magnetic resonance phenomena have been observed at the same time in the same magnet. The phenomena involved are indicated in Figure 2. The precession of the proton moment [Figure 2(a)] we have already described; it is detected and measured in a nuclear induction experiment. The electron has an intrinsic spin and magnetic moment and also precesses in a magnetic field [Figure 2(b)]. For the same field strength, the electron's spin-precession frequency is about 700-times greater than the proton precession frequency. A bare proton, moving in a magnetic field, revolves in a circular orbit with a certain frequency [Figure 2(c)]. This is the familiar principle of the cyclotron and we might name the associated frequency the

**Figure 2** Four elementary magnetic resonance phenomena

'proton cyclotron frequency'. A free electron in a magnetic field likewise revolves in a circular orbit, with a frequency that we may call the 'electron cyclotron frequency'. These 'cyclotron frequencies' are governed simply by the particle's charge-to-mass ratio. If any pair of these resonance phenomena are compared, in the same magnetic field, the field strength cancels out and we are left with a relation between certain atomic constants. The experiment is thus reduced to the measurement of a frequency *ratio*.

The ratio of the proton spin-precession frequency to the proton cyclotron frequency has been determined by Hipple,⁴ and by Bloch,⁵ in ways very different but equally ingenious. (The direct result of this measurement is the value of the proton moment in nuclear magnetons.) In my laboratory we have measured the ratio of the proton precession frequency to the cyclotron frequency of free electrons.⁶ The precession of the spin of a truly free electron has not been observed, but Kusch and his collaborators at Columbia, by combining the techniques of atomic beams and nuclear induction, have determined very precisely the ratio of the proton's precession frequency to that of the spinning electron in the hydrogen atom.⁷ The results of these experiments have in one way or another improved the accuracy of the following constants of atomic physics: the Faraday, F ; the specific charge of the electron, e/mc ; the ratio of the mass of the proton to that of the electron, M/m ; the dimensionless *fine-structure constant*, $2\pi e^2/\hbar c$. They have also helped to test the new theoretical advances in quantum electrodynamics led by Schwinger.

We turn now to a very different subject, one whose rapid growth was surely not anticipated at the beginning of this work. That is the study of nuclear magnetism for the light it can throw on problems of molecular structure and molecular motion, problems rather close to physical chemistry. Indeed certain branches of this work are now being pursued in chemical laboratories. We are interested not in the mere occurrence of nuclear resonance at a particular frequency but in its finer details. The variety that we find is suggested by Figure 3. Here are shown several lineshapes typical of the proton magnetic resonance in a few simple substances. One way to record such a spectrum is to hold the applied magnetic field constant while slowly varying the frequency of observation. In every case the center of the resonance absorption occurs

Figure 3 Lineshapes typical of the proton resonance in various substances. The line in water is not drawn to scale; it is actually much narrower and more intense than indicated

at very nearly the same frequency, in these substances. The linewidth, on the other hand, varies from some 50 kc s^{-1} , in the case of ice at low temperature, to less than a few c s^{-1} , in the case of a liquid like water. (The true width of the resonance in water is too small to be shown properly in the diagram.)

The effects shown here can all be traced to the action of the nuclear magnets on one another. In ice, each hydrogen nucleus is subjected not only to the field of our magnet, which might be several thousand gauss, but to the small magnetic field caused by each nearby proton in the crystal. Each nearest neighbor produces a field of a few gauss, more or less random in direction, with the result that the resonance absorption for the crystal as a whole is spread out over a corresponding interval in frequency. These 'local magnetic fields' are present in water, too, but their effectiveness is destroyed by the rapid molecular diffusion characteristic of a liquid. Two adjoining molecules remain neighbors so short a time (about 10^{-11} s) that their mutual influence is very slight. Thus *molecular motion* is the key to the striking difference between crystals and fluids in respect to the width of the nuclear magnetic resonance.

In many crystals, atoms or molecules occasionally jump from one position to another. Although such events are rare by most standards, they may occur frequently enough to affect the width of the nuclear resonance line. In ice, for instance, the line is distinctly narrower at -10°C than at a much lower temperature. The narrowing indicates that each hydrogen atom undergoes a displacement within the crystal lattice several thousand times per second. The motion involved here is not the familiar thermal vibration of an atom in a perfectly elastic crystal, but an abrupt shift to a new site. Nuclear resonance studies have disclosed many unsuspected internal motions in crystals, and have helped to reveal the exact nature of motions already suggested by other physical or chemical evidence.⁸

If the magnetic nuclei in a crystal are clustered together in pairs, the action of the nuclear magnets on each other causes a doubling of the magnetic resonance line. Further distortion is caused by more remote neighbors, and the width of the pattern as a whole depends on the orientation of the nuclear pair with respect to the magnetic field. Rather complicated effects are possible, some of which are illustrated in Figure 3. From a complicated effect that is also well understood, one can usually get a good deal of information. These magnetic

interactions are now rather well understood. I shall mention only one recent application of the technique to a chemical problem.

Groups of three equidistant protons in randomly oriented crystals give, characteristically, a line with three humps. The methylchloroform line, in Figure 3, is an example. We have a complete quantitative theory of this line structure.⁹ Last year Richards and Smith¹⁰ at Oxford, and quite independently Kakiuchi and others¹¹ in Tokyo, studied the proton resonance in perchloric acid monohydrate ($\text{HClO}_4 \cdot \text{H}_2\text{O}$) and certain related substances. This type of line was found. They were able to prove thereby that in those crystals the 'hydronium' ion, OH_3^+ exists, and to determine its dimensions. It is well known that hydrogen atoms are very hard to locate by X-ray diffraction. Here is an opportunity for nuclear resonance studies to supplement, in special cases, the more general methods of structure analysis.

Many nuclei have, in addition to an intrinsic magnetic dipole moment, an *electric quadrupole moment*. This is a way of saying that the electric charge of the nucleus is not distributed evenly over a sphere. One may think of the nucleus as either an elongated or a flattened ellipsoid. If such a nucleus is put into a nonuniform electric field, it experiences a torque, and precesses. (You will recall that the slow precession of the Earth's axis is a consequence of the ellipticity of the Earth and the nonuniform gravitational fields of the Moon and Sun.) The nuclei in many crystals find themselves in nonuniform electric fields arising from their immediate atomic surroundings. A nuclear electric quadrupole moment then manifests itself in a splitting of the magnetic resonance line. To put it another way, the energy associated with each of the possible orientations of the nuclear spin in a magnetic field is somewhat altered by the electric effect. This is illustrated in Figure 4. The trace in Figure 4 is the nuclear resonance spectrum of ^{23}Na in a crystal

Figure 4 A nucleus with an electric quadrupole moment in a uniform magnetic field (B) and a nonuniform electric field (ϵ). Lower trace: ^{23}Na resonance in a single crystal of NaNO_3 , showing splitting of magnetic resonance line into a triplet

of sodium nitrate. The line is widely split into a triplet by the quadrupole interaction. The number of components is always twice the nuclear spin I , so we have here a way of determining nuclear spins. This example is due to R. V. Pound who was the first to investigate these effects in crystals.¹²

Another interesting and fruitful branch of nuclear magnetism is the study of nuclear relaxation, by which I shall mean here the attainment of thermal equilibrium between the nuclear spins and their environment. Professor Bloch has already referred to the crucial importance of relaxation in all these experiments. In the first experiment of Torrey, Pound, and myself this question gave us much concern. Our approach was somewhat different from Bloch's and was based on a theoretical paper of fundamental importance by Professor Waller.¹³ Waller, in 1932, was dealing with relaxation in electronic paramagnetism, but Torrey was able to adapt his results to our case, with the conclusion that equilibrium should certainly be reached within several hours. We then designed the experiment so that, even if so long a time were required, the resonance could still be detected. As it turned out, the precaution was unnecessary, but that was our introduction to a fascinating problem that has occupied our attention ever since.

I believe we now have a good understanding of nuclear relaxation in many —though not all—physical systems. Experimentally, we find that the time to establish thermal equilibrium ranges widely from hours, in some substances, down to fractions of a millisecond in others. I show only one example, and that mainly to clarify the meaning of the term relaxation. Figure 5 is a plot of the gradual approach to equilibrium magnetization of an originally unmagnetized crystal of ammonium bromide. This can be called, quite properly, a *cooling curve*. The nuclear spins, in order to align themselves with the magnetic field, must give off energy to the crystal lattice. They are coupled so weakly to the lattice that the transfer of energy takes more than several minutes. Actually the approach to equilibrium is exponential, and the corresponding time constant, in this example 32 s, is what one calls the spin–lattice relaxation time.

It may seem astonishing, at first, that so long a time is associated with an atomic process. But in fact, if one looks at the problem more closely, it is hard to understand why the

Figure 5 The gradual approach to equilibrium magnetization. The ordinate is proportional to the intensity of nuclear polarization

time is not much *longer*. Moreover this crystal, at a somewhat higher temperature, has a relaxation time of only 0.01 s! The explanation of this, and of similar behavior in a wide class of substances, lies in internal molecular motions other than mere vibration. It is closely connected with the cause of line narrowing, mentioned earlier. The particular motion occurring in the ammonium halides is a sudden rotation of the whole tetrahedral ammonium ion inside the cubic unit cell.

We have now a fairly general theory of nuclear relaxation,¹⁴ a theory that has proved reliable enough to allow one to draw conclusions about the nature of the internal motion in a substance from the observed nuclear relaxation. My early collaborator, N. Bloembergen, has made essential contributions to this subject. Experimental work at Oxford and at Leiden has added much to our knowledge of other aspects of nuclear relaxation. In many respects this is only a new branch of a somewhat older subject, paramagnetic relaxation, in the study of which the Dutch laboratories and especially Professor Gorter, have long led. The problem of nuclear relaxation has a special attraction for the low-temperature physicist, because, as Professor Simon pointed out many years ago, nuclear magnetization offers a way toward extremely low temperatures, providing the nuclear spins can exchange heat with something else.

There remain several puzzling aspects of nuclear relaxation. In trying to understand them we find ourselves still returning to some of the ideas advanced 20 years ago by Professor Waller. While I speak of theoretical contributions to nuclear magnetism, I must mention also Professor Van Vleck, who has put the theory of linewidth on a rigorous basis, a notable advance.¹⁵

It is an old story in physics that higher resolving power leads to new effects. We remember that the magnetic moment of the nucleus was itself discovered through the hyperfine structure of lines in the visible spectrum. The nuclear resonance line in a liquid or gas can be remarkably narrow, as you have already seen. As soon as the reason for this was recognized, it became clear that the only practical limit on resolution was the inhomogeneity of the magnetic field applied to the specimen. Efforts were made in many laboratories to improve the magnets, and to use smaller specimens as well. With the improved resolution, it was found that identical nuclei, in the same applied field but in chemically different molecules, do not precess at exactly the same frequency. The explanation is simple: the magnetic field at an atomic nucleus differs slightly from the field externally applied because of the shielding effect of the electron cloud around the nucleus. In different molecules the atom's electron configuration will differ slightly, reflecting differences in the chemical bond. The resulting resonance shifts have been called 'chemical shifts'. They are only a nuisance to the experimenter interested in exact ratios of magnetic moments. But they are interesting to the physical chemist because they reveal something about the electrons that partake in the chemical bond.

No laboratory has more assiduously pursued high resolution than Professor Bloch's, where the striking example shown in Figure 6 was discovered.¹⁶ This is the proton resonance in ethyl alcohol, seen under very high resolution. Each line comes from a chemically equivalent group of protons in the molecule, the intensity being proportional to the number of hydrogen atoms involved, 3 (methyl group), 2 (CH_2 group), and 1 (hydroxyl), respectively.

Figure 6 The proton resonance in ethyl alcohol, observed with high resolution. The three lines arise from the CH_3 hydrogens, from the CH_2 hydrogens, and from the OH hydrogen, respectively

I can now return to the splitting observed in the proton and deuteron resonances in Figure 1. This splitting does not arise from any effect on the applied field, but from an indirect coupling of the proton to the deuteron through the medium of the two electrons in the HD molecule. It is as much an intrinsic property of the HD molecule as is the optical spectrum of the molecule.¹⁷ The splitting amounts to 43 c s^{-1} . I am sure we have only begun to explore the domain of very weak interactions—the ‘audio spectrum’ of molecules, if I may call it that.

This has been a long story and a complicated one. We are dealing not merely with a new tool but with a new subject, a subject I have called simply nuclear magnetism. If you will think of the history of ordinary magnetism—the electronic kind—you will remember that it has been rich in difficult and provocative problems, and full of surprises. Nuclear magnetism, so far as we have gone, is like that too.

Radda, George K.: The Development of In Vivo NMR in Oxford

George K. Radda

Oxford University, Oxford, UK

THE BEGINNINGS

Claiming priorities in scientific discovery is fraught with dangers, in that many discoveries are done at about the same time by several groups often working independently. Nevertheless, the paper from Oxford by Hoult et al., in 1974 is regarded by many as the beginning of in vivo NMR spectroscopy.¹ Admittedly, there were other publications before on cells and particularly one by Moon and Richards² where they introduced the idea that ^{31}P NMR can be used to measure intracellular pH values.

The Oxford work, like many other firsts, resulted from a set of happy coincidences and some bright ideas by clever young people. The environment was right to make new types of NMR measurements. The Oxford enzyme group had pioneered biological NMR in the 1970s and Rex Richards and his group, who made major contributions to the development of NMR instrumentation, and in particular to the use of superconducting magnets in Oxford, had moved into the Department of Biochemistry. My own group and his had been collaborating for some time in investigating biological membranes by phosphorus NMR and indeed had published several papers on bilayer structures, lipid asymmetry in vesicles, and the presence of chemical shift anisotropy in the phosphorus spectra of lipid bilayers arising out of a set of orientations.

We were more concerned at that time with enzyme regulation and, in particular, we had a long-standing interest in the mechanism by which phosphorylase *a* and *b* were controlled. We had done a series of NMR, spin-label and fluorescent studies, measuring the interactions of many ligands with phosphorylase and came to the conclusion that we were ready to predict how the enzyme should behave in vivo. When we did the appropriate calculations, we found that we were at least an order of magnitude out in our predictions, and this generated a lively discussion in the laboratory concerning what the difference might be between enzyme activities in solutions and those inside the living muscle.

It was during one of these discussions that I believe Steve Busby, one of our graduate students then, suggested that we should try and study the enzyme or at least some metabolic features of the enzyme in vivo in skeletal muscle by NMR. Although there were the usual objections as to why the experiment would not work, Busby, David Hoult, and others went away and obtained a small piece of muscle from the hind leg of a rat and did the first phosphorus NMR study on an intact piece of rat muscle. Immediately we observed high-resolution signals and it was relatively easy to identify these as coming from the major phosphate-containing metabolites: ATP, phosphocreatine and inorganic phosphate. As the muscle

Figure 1 First ^{31}P NMR spectra from tissues. (Reprinted with permission from *Nature*, Ref. 1)

became anoxic in the NMR tube, the changes in the spectra observed were what one might have expected, and indeed the shift in the phosphate peak showed that the muscle became acidic (Figure 1).

This was a very exciting observation and needed to be done correctly, so we tried to repeat the experiment many times before it worked again, largely because of spectrometer problems. The results were however consolidated and essentially the first set of observations explained why the phosphorylase activity we calculated was higher than that observed in vivo. This arose from the fact that the inorganic phosphate signal measured by NMR was considerably lower than the analytical values obtained previously by freeze extraction. So we had got an answer to the question we set out to investigate, namely, that the K_m value of phosphorylase for phosphate in vivo was much higher than the available phosphate concentration inside the resting muscle cell. We also recognized the general importance of our work for the study of metabolism in muscle and submitted a paper for publication in *Nature*. The manuscript was rejected on the grounds that it described highly specialized experiments, unlikely to be repeated in other laboratories and of no general interest. I think this was the only time in my scientific career that I appealed against an editorial decision. I explained in my letter that we had talked about this work already in a number of places, particularly in the United States, and it created a great deal of excitement. The Editor accepted our argument and published the paper.

FROM MUSCLE TO THE HEART

The results of these first studies were actively pursued by members of the two groups and we investigated perfused adrenal glands, developing frog embryos, and various skeletal muscle preparations in which we studied compartmentation of metabolites, intracellular pH, and the interaction of free ATP with magnesium. After the publication of our first paper and talks given at international meetings, a number of people had approached us with the possibility of some collaborative programs. Of these, in particular, Professor Doug Wilkie and Dr. Joan Dawson, well-known experts on frog muscle

from University College, London, collaborated with David Gadian and solved the physiological problem of keeping muscles oxygenated and contracting by using small muscles and carrying out the experiments at 4 °C. Also in 1976, Britton Chance came over and we carried out the first series of experiments on a small rat heart which could be placed into the 8-mm NMR sample tube that was contained within our existing magnet (Figure 2). This work, published in the *Proceedings of the National Academy of Sciences USA*, formed the background to a joint proposal between Britton Chance and myself to NIH to set up a collaborative program on cardiac bioenergetics.

It was at about this time that Pamela Garlick from the cardiovascular unit of the Hammersmith Hospital, directed by Professor J. P. Shillingford, had joined us as a research assistant, supported by the Science Research Council. Her experience on perfused hearts became important and she managed to perfuse mouse hearts in the 8-mm sample tube, keeping them alive and beating. Although these spectra and these studies were never fully published, they have appeared in several proceedings and book chapters as illustrative of the kinds of phosphorus spectra one could obtain from a live heart.

Again, Chance participated in our first experiments on perfused rat hearts, small enough to be put inside the 8-mm tube. These were done towards the end of 1976, when Chance became aware of similar interests at Baltimore. Indeed the excellent and objective book by Don Hollis under the title 'Abusing Cancer Science' described how they first started phosphorus NMR on perfused hearts with Bill Jacobus following a visit to Baltimore by Bob Shulman who gave a talk about phosphorus NMR in *E. coli*. So these two groups worked on the same problem independently, but they communicated to us the contents of their paper, on perfused rat heart, which they published in *Nature*. We were able to refer to this work prior to publication in our own paper that was published in *Biochem. Biophys. Res. Commun.* the same year, that is in 1977.

The realization that we could do the physiology much better and study adult rat hearts if we were able to put a much larger sample tube into our magnet, led us to a proposal to the British Heart Foundation requesting support for the construction of a new wide bore high-field superconducting magnet, specially designed by Oxford Instruments, for biochemical investigations of the heart. As far as the British Heart Foundation was concerned this project was a bit of a gamble, and they sent down to Oxford two eminent professors of cardiology to investigate what this was all about. After all, no one had asked them before to pay £25 000 for some niobium/titanium wire from which a magnet would be wound. Sir John McMichael, then a retired Professor of Cardiology, previously at the Hammersmith, and Professor Peter Sleight, Professor of Cardiology at Oxford, came to the laboratory and Pamela Garlick managed to show them a perfused mouse heart beating in the spectrometer and the way the spectrum was built up by repeated Fourier transform scanning. We then turned off the oxygen supply and they watched, admittedly with a rather poor time resolution, the disappearance of phosphocreatine and eventually of ATP during the ischaemic period.

Sir John McMichael went back to the British Heart Foundation very excited about the possibilities of looking at the biochemistry of the intact animal heart and recommended support for our venture. With help from Rex Richards and others, and Oxford Instruments, a new magnet was designed

and very rapidly constructed. We had the system in the laboratory and working by mid-1977. Our NIH application with Britton Chance was also successful, and we began our joint collaboration using NMR of perfused organs. Our 180 MHz 4.2-T wide bore magnet was used for a whole range of experiments over the next 15 years, when we replaced it with a higher field system.

More work on perfused hearts was followed by a completely new study on transplanted kidneys in the rat, carried out by a surgeon, Peter Bore, who used to come down from Liverpool often after having finished a human renal transplant operation, working in close collaboration with Peter Sehr and John Seeley. Chance, joined by Ian Silver from Bristol, came to try some ^{31}P measurements on excised animal brain, but we couldn't keep them alive long enough. Eventually we studied brain from hibernating hedgehogs as the cooled brain lasted long enough to give good ^{31}P NMR spectra. The results were presented aptly in 1979 at a symposium honoring Mildred Cohn. Much of this early work, including references to results of other groups, can be found in *Annual Reviews of Physiology*.³

FROM THE SURFACE COIL TO HUMAN MUSCLE

Two American postdocs joined the program in 1978/9, Jo Ackerman and Tom Grove. Following the kidney transplantation experiments, we decided to try and detect metabolism in vivo inside the animal following surgery. Gordon Wong, a graduate student, together with other members of the group tried to use solenoid coils to look at kidneys in animals but was unable to eliminate signal from adjacent muscle. It was on the basis of this experiment that the suggestion was made that we should just simply squash the solenoid coil into a single loop and try to look at the kidney that way. This was the idea of the surface coil that Jo Ackerman and others immediately used for demonstrating that muscle and brain metabolism in the intact rat can be quantitatively studied in this way.

This exciting experiment was written up for *Nature* and indeed published there, but not until we had sought advice about its potential patentability.⁴ The National Research and Development Corporation who was the government organization advising all the research grant holders on these matters, told us that the idea and experiment were not patentable. Looking back and looking at the wide use of surface coils now, both in imaging and spectroscopy, we wonder how sound that advice was in 1979.

The use of surface coils, however, yet again transformed completely the possibilities of in vivo spectroscopy. Chance again visited us and saw the experiments we had done on skeletal muscle. I drove him back to Heathrow airport where we had a long wait for his flight and we discussed what possibilities might arise from the use of such surface coils. It was, I believe, then, at Heathrow airport, that we came to the conclusion that it ought to be possible to investigate human limbs if only we had a horizontal very wide bore, high-field magnet available. Chance suggested that it would be of considerable interest to study patients with peripheral vascular disease and map out where metabolism showed irreversible or reversible damage in the muscle. This measurement could help the surgeon in deciding whether or where to amputate.

Figure 2 The 8-mm probe and part of the 7.5 T superconducting magnet used for the first and early isolated tissue and organ experiments

I would give my right arm for the progress of NMR
 I actually died on May 5 1981
 With greetings to a wonderful team
 A. Abragam

Figure 3 A ^{31}P NMR spectrum of the arm muscle of Anatole Abragam

Both Chance and I approached Oxford Instruments, and with their help a new magnet was designed to operate at 2 T in a horizontal configuration with a clear bore of 30 cm. One of these magnets was delivered to Philadelphia and the other to Oxford, again following support from The British Heart Foundation for this stage of the development. But prior to this, Philadelphia already had a small bore (18 cm) horizontal magnet and Chance managed to put his leg inside it and obtained a ^{31}P NMR spectrum. The resolution was not very good but Chance's leg in the magnet impressed the *Proceedings of the National Academy of Sciences USA*, where the first spectra were published. The work done in Oxford initially in collaboration with Wilkie and Dawson on arm muscles appeared in the *Journal of the Physiological Society* in 1980.

THE FIRST CLINICAL RESULTS

Having demonstrated the feasibility of obtaining phosphorus spectra on human arms and legs, we decided to embark on a clinical program on muscle diseases. This required that we should build up a team consisting of clinicians as well as biochemists and physicists and move our magnet to a hospital environment. This was achieved following support from The

British Heart Foundation and now also the Medical Research Council in early 1981.

In the meantime, we investigated our first patient on 26 January 1981 at 11.45 a.m. (in those days we took very detailed notes), with the magnet still being in the Department of Biochemistry. This was the patient who was shown to have McArdle's Syndrome, i.e. a lack of phosphorylase activity, who showed a clear absence of acidification during exercise. The results of this study, the first clinical study using magnetic resonance spectroscopy, were published in the *New England Journal of Medicine*.⁵

Having moved to the Radcliffe Infirmary in April 1981, we were ready to get down to investigating a whole range of muscle diseases in earnest. We had many interested visitors to see the set-up in the hospital and we took these opportunities to add another control subject to our records. One of these was Anatole Abragam, whose remarks and muscle ^{31}P NMR spectrum are shown in Figure 3.

In order to enhance our interaction with the clinical community, we had a number of open discussions and instituted our Friday morning 8 a.m. clinical meetings. Our first record for these meetings goes back to 5 June 1981 and we have kept up these weekly discussions as well as detailed records of all the patients we have studied since then. In parallel we continued to support the clinical studies with

investigation in the laboratory, on animal muscle, heart, brain, and kidney.

EXPLORING ^{31}P NMR

The period of 1979–82 saw a whole range of new experiments and exciting visitors to the laboratory. Among these, Tom Grove was able to do the first open-heart surgery on an animal and measure metabolic response in the live heart. In vivo kidney experiments brought Bob Balaban and Sheldon Adler to join the group to try and apply some of the methods to renal biochemistry and medicine. Sheldon Adler took a great interest in the clinical developments and contributed much to the early discussions on the design of patient studies. The clinical program owes much to Doris Taylor and Peter Styles, now tenured members of the MRC Unit, and past members, David Gadian, Peter Bore, and Brian Ross.

Professor George du Boulay, the distinguished neuroradiologist from London, came to do some experiments with us and collaborated with Keith Thulborn on measurements of blood flow and metabolism in stroke models in the gerbil and on a monkey. Keith Thulborn's early work with Peter Styles and John Waterton, who is now running the NMR facility at ICI, on flow and oxygenation of the blood formed the basis of the now widely quoted mechanism for susceptibility effects in functional imaging, the work having been published in 1982. In the meantime, soon after the muscle measurements with Doug Wilkie, Truman Brown (then at the Bell Laboratories) came over to help us with the first saturation transfer studies on the creatine kinase reaction in skeletal and heart muscle. The results were reported at Britton Chance's 65th Birthday Symposium in Philadelphia in July 1978.

Of course, others elsewhere, Bottomley and Nunnally in Baltimore, Ingwall in Harvard, were also close on our heels or maybe in parallel doing magnetization transfer experiments. On the perfused heart work, Arnie Schwartz from Cincinnati, Andi Seymour, and Steve Williams have all made major contributions in establishing the technique as a valid physiological and biochemical tool to study the pharmacology as well as basic control features of the heart. Paul Matthews joined the group in this work.

The comparison of control of cardiac and skeletal muscle energetics, as studied by Eric Shoubridge in animals where phosphocreatine was depleted and by Paul Matthews in the heart, was followed by the development of detailed exercise protocols for humans in what we called the Clinical Magnetic Resonance Laboratory at the Radcliffe Infirmary. These protocols were used to study groups of carefully selected patients with, for example, mitochondrial myopathies, muscular dystrophies, and a whole range of other conditions. These early results were already well documented and are still often used by us in comparative analyses of the extensive patient data base which we have now accumulated.

BIOCHEMISTRY OR MEDICINE?

For a biochemist with no knowledge in medicine, the possibility of leading a team investigating clinical problems has been both daunting and exciting. It was a happy

coincidence that with a long-standing interest in the control of phosphorylase and glycogen metabolism, the first patient we examined had phosphorylase deficiency. But the decision to take on the commitment of a clinical NMR spectroscopy program was no coincidence and required much preparation and thought.

I personally spent a year (1978–79) talking to various clinicians getting their views, and to my own group involved in the NMR studies, to decide whether we were the right people to set up a clinical research facility if funding was available or whether we should stay with the basic biochemical investigation and pass on to someone else the possible development of a clinical facility. We had no experience in medical matters except for our collaboration with clinicians in our work on heart and kidney. A key meeting took place on 28 November 1979 at Wolfson College, Oxford on the 'Applications of NMR to Medicine'. The purpose of this meeting was to discuss the potential of spectroscopy in clinical research and clinical practice. The participants, by invitation only, included members of my own research group, seven representatives of the English, Scottish, and Welsh Health Departments, officials from the Medical Research Council (MRC), key individuals from Oxford Instruments, who were considering setting up a separate company to develop systems for clinical spectroscopy, and a number of clinicians (largely from Oxford). Talks were given by David Gadian (introduction to NMR), Derek Shaw, Oxford Instruments, now GEC (methods in medical NMR), myself (^{31}P NMR in biochemistry), Peter Hanley, Oxford Instruments (magnets for whole body ^{31}P NMR), Peter Bore (medical applications), and concluding remarks by Rex Richards. There followed an extensive discussion on important clinical problems where spectroscopy might be useful, with significant contributions from John Ledingham (now Associate Clinical Director of my MRC Unit), Bheeshma Rajagopalan (now Senior Clinician in my Unit), and Brian Ross; Roy Gordon from Oxford Instruments (now Bruker) was also present.

The outcome of this meeting was that we decided to try and develop clinical phosphorus spectroscopy, with the 30-cm bore topical magnetic resonance system being an intermediate stage to the final 60-cm whole body magnet. Oxford Instruments set up Oxford Research Systems, the Department of Health agreed to contribute funding and the MRC were going to evaluate a scientific proposal from us. The story of the 2-T small system (we called it Stage 2) has already been given above.

CLINICAL SPECTROSCOPY ON THE WHOLE BODY MAGNET

Once the MRC decided to fund our program, and the cost of the whole body magnet was secured jointly from the Department of Health and the Department of Trade, we could plan for Stage 3. The MRC paid for the cost of a building and the Regional Health Authority, together with the University, agreed to assign a prime site at the John Radcliffe Hospital where our temporary building (temporary in the sense that it was designed for about 10 years) could be put up.

It was at that point that, with MRC support, Bheeshma Rajagopalan joined the team and both he and Peter Styles were appointed by the Medical Research Council to tenured posts.

Thus the core team consisted of a physician, a physicist, and a biochemist (myself). We were also given support to build up a team around these three people. The building operation and the 2-T magnet construction commenced in the middle of 1982. By March 1983, the new Clinical Magnetic Resonance Facility at the John Radcliffe Hospital was completed and the magnet was delivered to the facility in the autumn of that year. The setting up of the system was entirely Peter Styles's responsibility and within a relatively short period we were examining human volunteers by ^{31}P NMR, starting with members of the group and the laboratory. Our records show that the first patient was investigated on the 6 January 1984 in this new clinical building, a patient that had previously been studied in the small magnet with a muscle problem that we later identified as being a deficiency of the sarcoplasmic reticulum Ca^{2+} ATPase.

Styles and C. A. Scott (Rutherford Appleton Laboratory) and later a D.Phil. student, Martin Blackledge, developed rotating frame and depth selection techniques to investigate organs inside the human body in addition to the volume selection technique of topical magnetic resonance that was available at the beginning of the set-up. An early recognition of a cerebral mitochondrial disease was followed by studies on liver diseases and a variety of brain tumors and brain disorders, largely orchestrated by Rolf Oberhaensli who joined the group in 1984. Rotating frame one-dimensional imaging on the liver demonstrated by Styles and Scott was published in 1985, and the method became extensively used to investigate brain and later heart in human volunteers and patients.⁶

Throughout the period the generous support of The British Heart Foundation was available and, indeed, in 1984 with the new building and the new magnet being available, The British Heart Foundation set up a group—The British Heart Foundation Clinical Magnetic Resonance Group—and later established a chair of Molecular Cardiology in the University of Oxford for myself which commenced in 1984. This, together with program grants support from the Medical Research Council and the early success of the method, has established us as a credible research unit within a major clinical medical school with no responsibilities towards diagnosis and patient care. Our clinicians, in particular Bheeshma Rajagopalan, have participated and continue to participate in clinical work in the hospital on a voluntary basis, and this helps enormously with the continuation of the smooth contact between the basic research group and clinicians responsible for patients in the hospital.

THE MEDICAL RESEARCH COUNCIL UNIT

On the 1 April 1988, the MRC set up a new unit for us, the Biochemical and Clinical Magnetic Resonance Unit. We continued to operate on two major sites, in the Department of Biochemistry in the University and at the John Radcliffe Hospital in the Clinical Magnetic Resonance building. The unit works together with the British Heart Foundation Clinical Magnetic Resonance Group. Our primary aim is to investigate the biochemical basis of human disease processes through the development and application of NMR spectroscopy in vivo.⁷

As of now, August 1993, we have detailed records of close to 4000 patient investigations by ^{31}P NMR. The overriding

consideration in achieving our aim, however, is the close integration of the basic scientific work with the clinical program. This requires regular discussions, collaborative projects within the unit, and some organizational help. On the last point, since the beginning of our clinical plans in 1980 we instituted an 'annual retreat' for the whole group, where everyone gives a talk and participates in the discussions. The first three of these were held in the oldest inhabited country house in England, Charney Bassett Manor in Oxfordshire, and nowadays they take place in a small Cotswold town. It is there that we evaluate our achievements and weaknesses in the past year and formulate strategy for the next.

With a new MRC Magnetic Resonance Spectroscopy building, and a new 2-T magnet from August 1992, the unit continues to learn new biochemistry using NMR and to investigate control, bioenergetics, and adaptation in health and disease.⁸

Acknowledgements

Many people have contributed to this development but the list would be longer than the article. Some special contributions were highlighted in the text. Here I wish to acknowledge the support of the late Professor Rodney Porter and also that of many clinical colleagues in Oxford. Only few people have seen the whole of this story, but all that participated at various periods will have benefitted from the willing help and dedication of Sue Bailey. In this unit the philosophy is that everyone contributes to the program, and that without the enthusiasm of the young students and postdoctoral fellows the work would be much less interesting.

The British Heart Foundation, the Medical Research Council, and many other private- and public-funding groups have given us financial support, for which I am most grateful.

Successively junior research fellow, lecturer (Biochemistry) and Professor (Molecular Cardiology) University of Oxford, 1962–present. Approx. 650 publications. Research specialties: in vivo NMR, clinical spectroscopy, control of bioenergetics.

Radeglia, Reiner & Jancke, Harald: The History of the NMR Laboratory in the Former Central Institute for Physical Chemistry of the East German Academy of Sciences in Berlin

Reiner Radeglia & Harald Jancke

In April 1964 a JEOL 60 MHz NMR spectrometer (JNM-3H-60) was delivered to the Berlin-Adlershof NMR Laboratory which at that time belonged to the so-called German Academy of Sciences, Berlin. This spectrometer was designed primarily for liquids, but it also came with a solids accessory. Although this event might be viewed as the birth date of our NMR laboratory, in fact it was not, since solid state, physical NMR research was already well under way in the laboratory of physicists I. Ebert and G. Seifert.

However, before describing further the chronological development of our laboratory, let us first paint a brief picture of the state of research in the natural sciences and the role of the Academy in the former East Germany (Deutsche Demokratische Republik, DDR). In 1964 the Berlin Wall was three years old. Although the bitterness of the East German people over this wrenching event was in sharp contrast to the hopes of the East German government, the people had a cautious optimism for a positive development in the economy and the government had high hopes for research in the natural sciences. The Academy, along with the teaching system, which was based on a Russian model, was comprised of a series of scientific research institutes. It was supposed to play an advanced, central role. In contrast to the universities, the political climate in these institutes was relatively liberal, although it did vary greatly from institute to institute and depended strongly on the personality of the institute director. For the economy in general, and hence also the Academy, there was a severe shortage of hard currency for investment. Modern research instruments could only be imported within certain limits. In addition, the government wished to minimize further embargoes and at the same time wanted to encourage their own manufacture of modern analytical instruments in the DDR.

Already in 1958 an Institute for Instrumentation Manufacture had been founded. In this Institute was located the 'Physical Methods of Analytical Chemistry' Division whose primary task, with the help of instruments imported from Western countries, was the methodical study of instrumentation and the development of applied research in order to keep abreast of state-of-the-art know-how in modern analytical instruments.

In 1961 H. Kriegsmann, a chemist, assumed the leadership of this group. He had broad experience in the characterization of inter- and intramolecular interactions in the area of organosilicon and organotin compounds. He had worked with both infrared and Raman spectroscopy as well as gas chromatography and had used a combination of these tools in

the characterization of complex molecular interactions. The chemist, G. Engelhardt, a student of Kriegsmann, and the physicist, W. Storek, who had experience in building NMR instruments, comprised the first laboratory team. Shortly thereafter the physical chemist, R. Radeglia, who had experience in NMR applications, and the chemist, H. Jancke, joined the group. The areas of research for this group included structural studies via normal high-resolution NMR spectroscopy and a wide range of applied experiments, as service work or in direct collaboration with colleagues from other Institutes of the Academy, from the Universities or from industry. The principal research work, which was decided in consultation with other laboratories of Kriegsmann's group, was: (i) the proof and characterization of intramolecular interactions of substituted silanes, especially through the use of one-bond carbon-hydrogen coupling constants [$^1J(^{13}\text{C}, ^1\text{H})$] and (ii) proton NMR chemical shift measurements for the quantitative characterization of intermolecular interactions as well as comparison with the results of other spectroscopic and thermodynamic methods (hydrogen bonds in alcohols and silanols, ASIS and LIS effects in merocyanines).

Thus, for example, we wanted to answer the question as to whether silanols were more strongly associated than the corresponding alcohols. In this case we measured the concentration and temperature dependence of the chemical shifts of the hydroxyl protons of $(\text{CH}_3)_3\text{SiOH}$ and $(\text{CH}_3)_3\text{COH}$ dissolved in inert solvents. It was found that the silanols were more strongly associated because of the formation of cyclic trimers.¹ In addition, heavy nuclei were also of interest, but only ^{31}P and ^{19}F were accessible experimentally. The isolation brought about politically became progressively more noticeable. Thus, it became much more difficult to invite Western colleagues and the ability to travel to Western countries was sharply limited to a small circle of scientists; anyone with an immediate or closely related family in West Germany was not even considered (in this respect, it was quite surprising that Engelhardt was permitted to collaborate on ^{31}P experiments with Fluck in Heidelberg in 1966). For this reason there was strong collaboration with other colleagues in other parts of the DDR. There was close and friendly contact with the new NMR laboratory of the Organic Institute (E. Gündemann) which carried out analytical structure measurements, and the Inorganic Institute (A.-R. Grimmer, D. Müller) which was especially interested in methods of structure analysis in solids. Various scientific contacts with friendly colleagues in the corresponding institutes of other Eastern block countries were especially fruitful. For example, there were very productive exchanges with J. Schraml (Prague), G. Schneider (Szeged), S. L. Spassov (Sofia), and Z. Kecki (Warsaw). These collaborations were an important source of information for us, since these colleagues, compared with us, could travel virtually 'freely'. The very close contact between Engelhardt and E. Lippmaa (Tallinn, Estonia) was especially important for our laboratory. With this collaboration it was possible for us to carry out experiments on the at-that-time rare nuclei carbon-13 and silicon-29. The first rare nuclei experiments were carried out in Tallinn using a continuous wave spectrometer with a signal averager.

The year 1970 was an interesting one for East Germany for two reasons: with the growing relaxation of the cold war tension, there developed a growing mistrust of all influences from the West. The official policy was called 'isolation'.

At the same time one still hoped for scientific stimulation of the economy. A reform of the Academy was instituted which was supposed to strengthen the political influence of the state (Communist) party in the Institutes and to encourage a change in research emphasis toward more applied problems of importance to the economy. Our research group, which in a roundabout way had long been attached to the Central Institute for Physical Chemistry, and especially Dr. Kriegsmann as its Director, was suspected of giving research results to Western colleagues. He was therefore at least guilty of espionage and of collaborating with 'enemies of the working class'. Although the investigation 'through proper channels' did not uncover any punishable deeds, further contacts with the West were forbidden and Dr. Kriegsmann and all of his co-workers were considered to be 'politically undependable'. That had a number of unpleasant consequences. For example, Radechia's recommended appointment as Professor of Physical Chemistry at Merseburg and Jena was not permitted. Scientific publications were in general not welcome from the group and were quite forbidden in 'Western' journals.

Fortunately, the close collaboration between Engelhardt and Lippmaa was not disturbed and in 1972, in spite of the problems, we were able to obtain a 100-MHz PFT-100 spectrometer with a Fourier transform accessory (also from JEOL) and a Nicolet NIC 1085 computer. As a consequence, the research program was broadened in a number of directions:

1. ^{13}C characterization of steric interactions (of steroids) and of π -electron systems (e.g. polymethines).
2. Development of FT NMR methods for quantitative analysis.
3. Development of relaxation time methods for the study of molecular dynamics.
4. ^{29}Si NMR for the characterization of substituted silanes, silicones, and silicon resins as well as silicates in aqueous solution.
5. Quantum mechanical theoretical interpretation of NMR parameters.

After the proton spectra of simple polymethines $\text{X}-(\text{CH}=\text{CH})_m-\text{CH}=\text{Y}$ with $\text{X} = \text{N}(\text{CH}_3)_2$ and O^- and $\text{Y} = \text{N}(\text{CH}_3)_2^+$ and O (cyanide, merocyanine, and oxonole) had been studied, one could test whether an analogous relationship for the π -electron structure held for the ^{13}C NMR parameters. After preliminary measurements carried out in Lippmaa's group, it was possible to show with the new spectrometer that there was a corresponding alternation of the π -electron density and the carbon-13 chemical shifts and the coupling constants $^1J(^{13}\text{C}, ^1\text{H})$.²

Kriegsmann and his group had been interested for a long time in the characterization of organosilicon compounds. Now through the use of ^1H NMR spectroscopy it was possible to analyze the complex isomeric structure of cyclosiloxanes. Indeed, the availability of silicon-29 NMR made possible a significant advancement in the description of silanes, siloxanes, and polyoxanes. At this time we were working in a large international 'family' [Harris (UK), Levy (USA), Marsmann (FRG), Schraml (Czechoslovakia) and Pestunovich (USSR)] in the development of liquid phase ^{29}Si NMR.

The silicon chemical shift is, in an especially sensitive way, dependent on the nature of long-range substituents. This observation led to hopes of great progress in the area of the chemistry of inorganic silicon compounds. It was now possible to develop a wide range of ^{29}Si NMR applications in very close collaboration between the Tallinn laboratory and Jancke,

Engelhardt, and the newly arrived physicist D. Zeigan.³ Since a MAS/CP spectrometer was available in Tallinn for high-resolution solid state studies, we developed a wide range of experiments for characterizing solid silicates, especially zeolites, which were of special interest for the Institute as adsorbents and catalysts.

As a result of the oil crisis in 1973, there was a widespread need to develop analytical methods for the detailed structure of oil and coal (the basic methods had already been developed in the 1960s). Because of the great expense of imported crude oil, there was very great interest in East Germany to make chemical use of the resources available from brown coal (a locally abundant, cheap, but high sulfur content, oil). The Academy was given the task of developing the analytical instrumentation for this work. In collaboration with the petrochemical industry, we developed methods for measuring the individual components through the use of a combination of the information available from both proton and carbon-13 spectroscopy.

The theoretical work was concerned with 'sum-over-states' calculations of coupling constants; this work was done in collaboration with Th. Steiger from the theoretical chemistry section of the Institute. The peculiar dependence of the silicon chemical shift on the electronegativity of the substituents in simple silane derivatives $(\text{CH}_3)_{4-n}\text{SiX}_n$ (with $\text{X} = \text{OCH}_3$, F and $n = 0-4$) was the source of much speculation about the role of $p_\pi-d_\pi$ bonding. Engelhardt wanted to present his new experimental results, including a theoretical interpretation, at the 1973 European Molecular Spectroscopy Conference in Tallinn. That was the stimulation for Radechia to develop a simple chemical shift model based on theoretical work of Letcher and van Wazer. His new model was able to explain silicon chemical shifts without the need for $p_\pi-d_\pi$ bonding. The physicist, Renate Wolff, developed this work further in her Ph.D. dissertation. Using better basis functions (CNDO/2), she was able to show the correctness of the fundamental importance of the role of the charge on the silicon atoms, the excitation energy, and the possible $p_\pi-d_\pi$ interaction.⁴

The PFT-100 spectrometer did not have a programable pulse sequence capability nor phase-shifting capability; consequently experiments such as APT (attached proton test) and spin echo refocusing experiments were not possible. Inverse gated decoupling experiments could not easily be undertaken because the decoupling rf power could not be turned on during the instrument dead time. In spite of this, one could, by selecting a correspondingly longer dead time, analyze CH_n functional groups (a version for poor people). In collaboration with other laboratories, which in the meantime had obtained more modern spectrometers, we were able to analyze such structural groups properly.

Two very joyful events lifted our hopes for the further development of the scientific life in our laboratory. Firstly, H. J. Osten was able to spend a year working with Cynthia Jameson (University of Illinois Chicago) as a postdoctoral fellow. Since numerous bureaucratic rules and regulations had to be overcome, the trip had to be postponed for a year. This collaboration was also extraordinarily productive in the year after his return and led to further collaborative work on the effects of molecular vibration and rotation on the chemical shift. Secondly, the long-awaited importation of a Bruker MSL 400 spectrometer for the study of both solid and liquid samples was finally realized. At last we had the capability to carry out

CP MAS experiments on zeolites and other solid samples in our own laboratory and to undertake the entire range of 2D NMR experiments.

Due to the relaxation of political tension and the success of the West in improving travel opportunities for East German citizens, Engelhardt had the chance to leave the restrictive regulations in the DDR and to move to West Germany. His book 'High-Resolution Solid-State NMR of Silicates and Zeolites', co-authored with D. Michel (Leipzig), was published from his new address and was a precursor of the reunification of Germany. But no one dared to look that far into the future and the colleagues that he left behind concentrated their work on the new spectrometer. The solid state spectroscopic work on the zeolites was continued by B. Zibrowius and W. Storek. Building on earlier work, the quantitative carbon-13 analysis of hydrocarbon mixtures took on a greater meaning. Dr. Radeaglia, who since 1975 had taught at the Technical University of Merseburg (a University devoted primarily to analytical topics including nitrogen-15 NMR and especially photo-CIDNP effects) had to cut back sharply his active participation in the laboratory in March of 1988 due to health reasons; his work in Merseburg was given up entirely.

The political turning point in East Germany began in the fall of 1989. Members of the NMR laboratories of the Academy played an important part in the process of making the Institutes more democratic. The fall of the Berlin Wall brought freedom to travel and one saw that the reunification of Germany might take place. Old and new contacts with colleagues in West Germany and indeed in the entire Western world could now develop unhindered by political directives, letter censorship, and other restrictions. There was a joyful wave of sympathy which expressed itself also in new computers, new programs, and other research needs, speaking invitations and so on.

For several years it had been possible, using various *ab initio* calculations, to calculate quite accurately the magnetic shielding of a resonant nucleus due to the effects of the electrons in a chemical bond and to predict the chemical shift with good accuracy. Using the IGLO program provided for us by Professor Kutzelnigg and with a grant from the Chemical Industry Foundation, we were able to obtain an IBM R/6000 workstation. With this we could make accurate calculations of the silicon-29 shielding. Of especial interest to us was the theoretical background of the linear relationship between the Si–O bond length and the parallel component of the silicon-29 chemical shift tensor of silicates with C_{3v} symmetry; this relationship had first been observed by Grimmer in the beginning of 1980 and since then many other similar observations have been made. The IGLO methods permitted an exact analysis of the parallel and perpendicular components of the shielding tensor, including the contribution of a single Si–O bond. The change of the Si–O bond length of the

symmetry axis causes a change in the electronic structure of the three remaining Si–O bonds, which in turn results in the observed change in the parallel components.

After the fall of the Berlin Wall, our group, which had been formerly headed by Kriegsmann, tried to decouple itself from the little-loved Institute and took the name 'Analytical Centre, Berlin'. The recommendation of the scientific council which had evaluated the East German scientific establishment after reunification, along with the influence of Kriegsmann, thankfully resulted in the establishment of a new department in the Federal Bureau of Materials Research and Testing. Our Division of Analytical Chemistry, although greatly reduced in number, is part of that organization and is responsible for structural and materials analysis. Naturally, a certain redirection of our work into materials research was necessary, but for the future we will be working in such classical fields as (i) characterization of zeolite systems, using, for example, aluminum-27 quadrupole spectroscopy, (ii) silicon-29 NMR characterization of ceramic materials and their precursors, (iii) *ab initio* (IGLO) theoretical calculations of silicon chemical shifts for improved interpretation of practical measurements, and (iv) methods development work in the area of measurement and analysis.

Biographical Sketches

Reiner Radeaglia. Diploma (Chemistry) 1961, Dr. rer. nat. (supervisor Kurt Schwabe) 1963, Technical University of Dresden. Central Institute of Physical Chemistry of the Academy of Sciences, Berlin (East) 1963–91. Dr. habil. Humboldt University, Berlin (East) 1969; Professor of Physical Chemistry 1988. Federal Institute for Materials Research and Testing (BAM), Berlin 1992–present. Approx. 300 publications. Research specialties: NMR parameters and molecular structure.

Harald Jancke b 1941. Diploma (Chemistry) 1965, Dr. rer. nat. (supervisor Heinrich Kriegsmann) 1965 at Humboldt University Berlin. 1965–92 Central Institute of Physical Chemistry of the Academy of Sciences, Berlin (East). Since 1992 in the Federal Institute for Materials Research and Testing (BAM). 80 publications. Research specialties: NMR analysis in organosilicon and hydrocarbon chemistry.

Ramsey, Norman F.: Origins of Magnetic Resonance

Norman F. Ramsey

Harvard University, Cambridge, MA, USA

INTRODUCTION

I started my Ph.D. research in the summer of 1937 with I. I. Rabi, approximately two months before he invented the molecular beam magnetic resonance method, so I had the good fortune to write the first Ph.D. thesis based on magnetic resonance.¹ As a result I anticipated questions in my oral exam on the origins of the idea of magnetic resonance and looked with interest into the early history.²

In this article I recount what I learned from these studies and supplement it with an account of developments in molecular beam magnetic resonance prior to the condensed matter nuclear magnetic resonance experiments of E. M. Purcell, F. Bloch, and their associates.^{3,4}

The first work on nuclear magnetic shielding also began in this early era, so I conclude the article with a brief historical account of the development of ideas about magnetic shielding and chemical shifts which underlie the uses of NMR in chemical analysis, biology, and medicine, and about electron-coupled nuclear spin-spin interactions.

EARLIEST SEARCHES FOR A DEPENDENCE OF MAGNETIC SUSCEPTIBILITY ON FREQUENCY

The earliest reported search for a dependence of magnetic susceptibility on frequency was that of Belz⁵ in 1922 with different solutions of paramagnetic salts. No frequency dependence was found. Acting on a suggestion of Lenz and Ehrenfest, G. Breit⁶ four years later also searched for such a frequency dependence but found none. Perhaps this disappointment contributed to Breit's decision to concentrate on theory, where he had a highly productive career.

SPACE QUANTIZATION WHEN THE DIRECTION OF A MAGNETIC FIELD CHANGES

Theoretical ideas about the magnetic resonance method trace back to early quantum theory speculations and experiments on the changes in space quantization when the direction of a magnetic field is changed. The problem was first posed and partially solved in 1927 by C. G. Darwin⁷ and his analysis was subsequently improved by P. Gutinger,⁸ E. Majorana,⁹ and L. Motz and M. Rose.¹⁰

In the period 1931–33, O. Stern, T. E. Phipps, and O. Frisch^{11,12} in Stern's Hamburg laboratory observed the changes in the space quantization when the direction of the

magnetic field was changed, but their observations agreed only partially with theory. I. I. Rabi¹³ pointed out that the discrepancy between theory and experiment was due to the neglect of nuclear spins in previous theories. Those theories had neglected nuclear effects because the magnetic moment of the nucleus is about 2000-times smaller than that of the electron. However, the spin angular momenta of nuclei and the electron are comparable in size, so the nucleus produces observable effects when the angular momenta are tightly coupled at low external fields.

Although the techniques of microwave spectroscopy are quite different from those of magnetic resonance, there is sufficient similarity to note that in 1933 Cleeton and Williams¹⁴ using magnetron-generated microwave electric fields observed a single broad spectral line corresponding to the tunneling transition of the NH₃ molecule at a wavelength of 1.1 cm. There were, however, no subsequent microwave spectroscopy experiments for the next decade, until the microwave absorption spectra of O₂ and H₂O were studied for radar purposes near the end of World War II and published^{15–17} in 1946.

Another different but related experiment during this period was that of Lasarew and Schubnikow,¹⁸ which showed at low temperature that the nuclear magnetic moments in solid hydrogen contribute significantly to the observed static magnetic susceptibility of solid hydrogen.

FIRST ATTEMPTS TO OBSERVE MAGNETIC RESONANCE IN CONDENSED MATTER

In 1936, using a calorimetric detection technique, C. J. Gorter¹⁹ successfully observed a frequency dependence of the paramagnetic relaxation of a number of alums. He found that the observed effects depend on the frequency, ν , as ν^x where x is a number, usually between 1 and 2; no resonance effects were observed. Utilizing the same calorimetric technique, Gorter¹⁹ attempted to observe a nuclear magnetic resonance for ⁷Li in LiCl or for ¹H in aluminum potassium alum, but found no resonances.

In 1942, subsequent to the success of the molecular beam nuclear magnetic resonance experiments, Gorter and Broer²⁰ reported unsuccessful attempts to observe nuclear magnetic resonance in powders of LiCl and KF as a frequency pulling of a self-excited oscillator as the applied magnetic field was moved through the resonant value. The reasons for the failures remain a mystery, but they are probably due to detection inefficiencies since Bloembergen many years later was able to obtain a resonance with one of the same crystals used by Gorter. The first published use of the name 'nuclear magnetic resonance' is in Gorter's 1942 paper²⁰ where he attributes the coining of the phrase to I. I. Rabi.

TRANSITIONS INDUCED BY PASSAGE OF MOLECULES THROUGH DIFFERENTLY ORIENTED MAGNETIC FIELDS

While Gorter was pursuing his unsuccessful experiments, I. I. Rabi²¹ and Schwinger²² were developing theories for

the transitions induced when atoms or molecules in a molecular beam traverse successive regions of space with different directions of magnetic fields. In his brilliant 1937 theoretical paper entitled 'Space Quantization in a Gyating Magnetic Field', Rabi²¹ assumed for simplicity that fields were oscillatory in time even though the application was to molecules moving through fields which varied in space rather than time. Consequently, the formulas in that paper are applicable to resonances with oscillatory fields and the paper, without alteration, provides the fundamental theory for all subsequent magnetic resonance experiments. However, the theoretical transition probability was written in a form which obscured its resonant nature, while the subsequent averaging over molecular velocities eliminated sharp resonances. Thus Rabi did not immediately recognize the advantages of fields oscillating in time rather than space.

MOLECULAR BEAM MAGNETIC RESONANCE METHODS

After writing his paper on the gyrating field, Rabi discussed with some of his colleagues the possibility of using oscillatory rather than space-varying magnetic fields, but his laboratory had a full program of important experiments so no experiments utilizing oscillatory fields were seriously considered during the first five months following the publication of his paper on the gyrating magnetic field. In September 1937, C. J. Gorter visited Rabi's laboratory²³ and described his brilliantly conceived but experimentally unsuccessful efforts²⁰ to observe nuclear magnetic resonance. Rabi then fully appreciated the advantage of using an oscillatory field and promptly invented the molecular beam magnetic resonance method. Two successful molecular beam magnetic resonance apparatus were soon constructed by Rabi,^{24,25} Zacharias,^{24,25} Millman,²⁴ Kusch,²⁴ Kellogg,²⁵ and Ramsey.²⁵ A schematic view²⁴ of the method is shown in Figure 1. In these experiments the atoms or molecules are first deflected by an inhomogeneous magnetic field and refocused by a second one. When a resonance transition is induced in the region between the two inhomogeneous fields, the final beam intensity is reduced by the failure of refocusing. As a result, when the oscillator angular frequency ω is equal to the Larmor angular frequency

Figure 1 Schematic diagram²⁴ showing the principle of the first molecular beam magnetic resonance experiments. The two solid curves indicate two paths of molecules having different orientations that are not changed during passage through the apparatus. The two dashed curves in the region of the B magnet indicate two paths of molecules whose orientation has been changed in the C region so the refocusing is lost due to the change in the component along the direction of the magnetic field. (Reproduced by permission of Oxford University Press from N. F. Ramsey, 'Molecular Beams', 1985, p. 159)

Figure 2 First observed nuclear magnetic resonance.²⁴ The refocused beam intensity is plotted for various values of the magnetic field; 1 A corresponds to about 1.84×10^{-4} T. The frequency of the oscillating field was held constant at 3.518×10^6 Hz. (Reproduced by permission of Oxford University Press from N. F. Ramsey, 'Molecular Beams', 1985, p. 161)

ω_0 of a nucleus in magnetic field B_0 , a sharp resonance is obtained for

$$\omega = \omega_0 = \gamma_I B_0 \quad (1)$$

where ω_0 is the angular precession frequency of a classical magnetized top with the same ratio γ_I of magnetic moment to angular momentum. Figure 2 shows the first reported nuclear magnetic resonance curve as obtained by Rabi, Millman, and Kusch²⁴ with a beam of LiCl molecules.

Kellogg, Rabi, Ramsey, and Zacharias^{1,25} soon extended the method to the molecules H_2 , D_2 , and HD. When these experiments were started, it was thought the only measurable interactions would be those of the magnetic moments with the external magnetic field, so that there should be a single resonance for each magnetic moment. Instead the authors made the unexpected discovery of multiple resonances as shown in Figure 3. They soon realized that these arose from internal interactions within the molecule and that the spacings of the resonances measure the molecular spin-spin, spin-rotational and nuclear quadrupole interaction energies. The transitions occur whenever the oscillatory frequency ω is at a Bohr angular frequency ω_0 for an allowed transition where

$$\hbar\omega = \hbar\omega_0 = E_i - E_f \quad (2)$$

For the first time, the authors described their results as 'radiofrequency spectroscopy'. The observed spectrum for H_2 is shown in Figure 3. These resonances were the first instances of multiple line spectroscopy with coherent electromagnetic radiation, a characteristic of subsequent radiofrequency, microwave, and laser spectroscopy

The first molecular beam magnetic resonance experiments were with $^1\Sigma$ molecules, but in 1940 Kusch, Millman, and Rabi^{26,27} extended the method to paramagnetic atoms

Figure 3 Radiofrequency spectrum of H_2 in the vicinity of the proton resonance frequency.²⁵ The resonance frequencies are determined primarily by the interaction of the proton magnetic moment with the external magnetic field, but the states of different m_I and m_J are displaced relative to each other by the different values of the nuclear spin-spin and spin-rotational interaction energies. (Reproduced by permission of Oxford University Press from N. F. Ramsey, 'Molecular Beams,' 1985, p. 6)

and in particular to $\Delta F = \pm 1$ transitions of atoms. For such transitions, the relative orientations of the nuclear and electronic magnetic moments are changed, so the resonance frequencies are primarily determined by the internal properties of the atom.

Essentially the same molecular beam magnetic resonance technique was utilized by Alvarez and Bloch²⁸ to measure the magnetic moment of the neutron with a neutron beam. The first publication on the neutron magnetic resonance came about two years after the first molecular beam magnetic resonance papers, so it is usually considered that the neutron studies of Alvarez and Bloch were merely adaptations of the resonance methods developed by Rabi and his associates. However, Alvarez has stated that Bloch thought of doing the neutron beam resonance experiment before either of them had heard of the earlier molecular beam resonance experiments. It must have been a bitter disappointment to Bloch and Alvarez to learn that their clever idea for magnetic resonance had been anticipated and it is to their credit that they did not let this blight their research careers; instead each went on independently to win Nobel Prizes for other research.

Molecular beam and neutron beam magnetic resonance experiments were interrupted by World War II. In 1944 Rabi and I spent one evening together in Cambridge, MA, planning possible post-war research experiments. Two ideas emerged as leading candidates. One was to test fundamental quantum mechanics by using the molecular beam magnetic resonance method to measure the theoretically predictable hyperfine separation in atomic hydrogen. This experiment was eventually carried out²⁹ and led to the first indication of an anomalous magnetic moment of the electron²⁹ and to the development of relativistic quantum electrodynamics (QED).³⁰ The second idea was to detect the existence of nuclear magnetic resonance transitions by their effects on the oscillator. To our pleasant surprise, the signal-to-noise calculations were favorable and we became enthusiastic about the possibility. Then, we realized we were merely reinventing Gorter's nuclear magnetic resonance experiments^{19,20} which had failed for unknown reasons. We, therefore, decided such

efforts should be given a lower priority than the atomic beam experiments.

ELECTRON PARAMAGNETIC RESONANCE EXPERIMENTS IN CONDENSED MATTER

Despite his unsuccessful efforts to observe nuclear magnetic resonance, Gorter¹⁹ successfully observed paramagnetic relaxation in condensed matter but his attempts to observe paramagnetic resonances failed. The first successful paramagnetic resonance experiments in condensed matter were those of Zavoisky,³¹ who in 1944 observed paramagnetic resonance with $CrCl_3$. Shortly after Zavoisky's pioneering work, other observations of electron paramagnetic resonances were made by Cummerow and Halliday³² and many others.

NUCLEAR MAGNETIC RESONANCE EXPERIMENTS IN CONDENSED MATTER

Following World War II, two groups independently developed nuclear magnetic resonance experiments with condensed matter and with detection of the resonance by the effect on the electromagnetic radiation. E. M. Purcell, H. C. Torrey, and R. V. Pound³ at Harvard University observed the nuclear magnetic resonance absorption of the applied electromagnetic radiation while F. Bloch, W. Hansen, and M. E. Packard⁴ at Stanford University observed the induced nuclear induction signal. Each group had different reasons for being willing to proceed with these experiments despite the failure of Gorter's earlier experiments.

Purcell, Torrey, and Pound³ were initially unaware of Gorter's failure. When Rabi learned of their plans and pointed out that Gorter's similar experiment had failed, Purcell was disappointed but felt that their feasibility calculations were favorable including an estimate by Torrey that the nuclear spin relaxation time was about 1 h. Furthermore the work on the new experiment had already gone so far that it should not be stopped. Purcell and his associates devoted special attention to problems of signal size and noise. On December 24, 1945 their letter³ was received by the *Physical Review* announcing the successful observation of nuclear magnetic resonance absorption of protons in a paraffin-filled 30 MHz resonant cavity whose output was balanced against a portion of the signal generator output. When the magnetic field passed through resonance, an unbalanced signal 20-times the noise was observed.

When Bloch, Hansen, and Packard⁴ started their experiments, they were fully aware of Gorter's failed experiments but they thought the failure was due to the relaxation time T_1 being so great that Gorter had not waited long enough. To overcome this difficulty they proposed putting their water sample in a strong magnetic field for several days to allow the nuclear spin system to reach thermal equilibrium. With their apparatus ready for a first test and the water inserted into the high magnetic field, they allowed several days for the system to come to equilibrium, while Bloch went off on a ski trip. When they finally observed the induction signal they learned that the long delay was unnecessary—the relaxation time was

short not long! A letter⁴ announcing their successful experiment was received by the *Physical Review* on January 29, 1946. It was soon realized that the two methods were alternatives for obtaining similar information and the general term nuclear magnetic resonance or NMR was applied to both.

CHEMICAL SHIFTS, NUCLEAR MAGNETIC SHIELDING AND ELECTRON-COUPLED NUCLEAR SPIN-SPIN INTERACTIONS

In the early days of molecular beam magnetic resonance experiments, it was recognized that the magnetic field at the nucleus of an atom was not the same as the externally applied magnetic field since the applied field induced a diamagnetic circulation of the electrons in the atom. In 1940, Lamb³³ developed the theory of this magnetic shielding for single atoms and tabulated atomic corrections based on Thomas-Fermi wavefunctions. Later, Dickinson³⁴ used Hartree-Fock wavefunctions for a better list of atomic corrections. Because of the lack of an alternative theory, these formulas were also applied to molecules. For atoms with many electrons this is a good first approximation since the inner core electrons contribute most to the shielding and the configurations for inner core electrons are similar for atoms and molecules. However, in a paper written in 1949, I noted that for atoms with few electrons this approximation was not valid and, even for many electron atoms, failures of the approximation would lead to different shieldings in different molecules.³⁵ In a series of papers,³⁵ I published general formulas for calculating the magnetic shieldings or chemical shifts in different molecules. These publications also pointed out that there could be shielding anisotropies and provided general formulas for calculating the anisotropies.

At about the same time, experimental evidence for shifts began to emerge. Bloembergen,³⁶ in an abstract published in 1949, noted that in $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ the constant magnetic field at the position of each proton in the unit cell is shifted by an amount which depends on the relative positions of the H and Cu atoms and increases with decreasing temperature in the same way as the total static magnetization. Knight³⁷ discovered that resonance frequencies for some nuclei are several tenths of a per cent higher when in a metallic state than when in the form of either powdered or dissolved salts.

Dickinson,³⁸ Proctor and Yu,³⁹ and subsequently many others experimentally found shifts of a few hundredths of a per cent in the NMR frequencies of the same nucleus in different chemical compounds, consistent with my general theory.³⁵ These shifts are the basis for the widespread use of NMR in chemical analysis, biology, and medicine.

Bloembergen and Dickinson⁴⁰ also observed that the NMR resonance frequencies of liquid samples are shifted when paramagnetic atoms are added to the samples to reduce the relaxation times, and that the magnitudes of the shifts are proportional to the ion concentrations.

Normally the magnitudes of the chemical shifts are temperature-independent but occasionally they are not, as first observed by Proctor and Yu⁴¹ and by Packard and Arnold.⁴² When the temperature shifts are small compared with the chemical shift, they can be accounted for by my general theory of chemical shifts³⁵ as due to different thermal excitations of

low lying molecular states. On the other hand, that theory did not directly account for Packard and Arnold's⁴² observation of a relatively large temperature shift for H in the OH radical of ethyl alcohol. However, Liddel and I⁴³ found that that experiment could be accounted for by modifying the usual theory of chemical shifts to take into account molecular association in liquid alcohol and its change with temperature.

A different frequency shift in NMR was discovered experimentally by Gutowsky, McCall, Slichter, and McNeil⁴⁴ and by Hahn and Maxwell.⁴⁵ They found a shift proportional to $I_1 \cdot I_2$ which they could not account for by any previously known interaction. Together with Purcell, I pointed out that this could be attributed to an electron-coupled nuclear spin-spin interaction.⁴⁶ Such a newly considered interaction could arise from each nucleus interacting magnetically with the electron spin of its own atom. Since the electrons are tightly coupled together by the exchange coupling that leads to zero resultant electron spin for most molecules, the nuclear spins are effectively coupled together. In a later publication,⁴⁷ I developed the theory quantitatively both for the observed scalar interaction as well as showing there could be an additional anisotropic electron-coupled spin-spin tensor interaction. Subsequent HD measurements agreed with theory.

From the time of the first NMR experiments and the establishment of the chemical shifts, developments in magnetic resonance advanced at a rapid pace. For this reason, it is appropriate to bring to an end this account of the origins and early history of magnetic resonance.

Biographical Sketch

Norman F. Ramsey. b 1915. B.A., 1935 and 1937, Columbia and Cambridge Universities, Ph.D., 1940, Columbia (supervisor I. I. Rabi), D.Sc., 1957, Cambridge. Higgins Professor of Physics, Harvard University, 1947–86; Emeritus 1986–present. President Universities Research Association, 1966–83. Research ranging from molecular beams to particle physics including first Ph.D. thesis using magnetic resonance, co-discovery of deuteron quadrupole moment, measurement of nuclear magnetic moments including proton, deuteron, and neutron, and first successful theories of the NMR chemical shift and of electron-coupled nuclear spin–spin interactions in molecules. Inventor of method of separated oscillatory fields and co-inventor atomic hydrogen maser. National Medal of Science, 1989 and Nobel Prize in Physics, 1989.

Randall, Edward W.: “Double, Double, Toil and Trouble” (Alias Double Resonance)

Edward W. Randall

University of London, Queen Mary College, London, UK

Although I worked in the room next to Rex Richards's laboratory at Oxford in the late 1950s, I did not start any magnetic resonance work until I joined Professor Gene Rochow at Harvard in 1959 as a postdoctoral fellow. There I began rebuilding a NUMAR instrument for solid state work which I eventually completed in late 1960. Meanwhile I did some ESR work with Gus Maki before collaborating with a recently arrived instructor, John Baldeschwieler by name, who was starting out on heteronuclear double resonance (d.r.). We collaborated, and my very first NMR paper (and one of John's) was entitled 'The Measurement of Chemical Shifts by NMDR'.¹ This 'indirect', now usually called 'inverse', method using $^1\text{H}\{^{14}\text{N}\}$ d.r. to measure ^{14}N shifts, was later exploited at Queen Mary College (QMC), where I went in 1961, by Duncan Gillies to map out ^{15}N spectra very accurately by $^1\text{H}\{^{15}\text{N}\}$ spin tickling.² At first, however, one of the main objectives was merely to sharpen up ^1H spectra by $^1\text{H}\{^{14}\text{N}\}$ decoupling so that they could be analyzed more easily. It was a great delight to me more than 30 years later to use exactly the same technique in $^1\text{H}\{^{14}\text{N}\}$ spin echo d.r. to *image* ^{14}N indirectly for the first time,³ and then to adapt this to spin- $\frac{1}{2}$ nuclei such as ^{15}N .⁴

The early CW double resonance experiments were sometimes truly two-dimensional although all of the 2(frequency)D space was rarely mapped out (except by Ray Freeman and ourselves), but of course it took the introduction of pulsed FT methods in the 1970s to really revolutionize 2D NMR.

John Baldeschwieler and I published a quite influential *Chemical Review* on d.r. in 1963, which among other things popularized the X{Y} nomenclature.⁵ The preparation of the review was a pleasure since it put us in touch with other double resonators. Notable was a personal communication from Paul Lauterbur on $^{13}\text{C}\{^1\text{H}\}$ nuclear Overhauser effects. In the UK, I visited that influential NMR group at Teddington headed by John Pople and David Whiffen, which included Keith McLauchlan and Ray Freeman. I was most grateful to that group for allowing my first research student, Tony Bourn, access to their ^1H homonuclear d.r. equipment, while my second and third students, Duncan Gillies and Derek Shaw, were building up our own spectrometer around a Mullard permanent magnet (at 0.9 T). Tony Bourn (R.I.P.) with Frank Anet later woke up the chemical NMR community to the benefits of the NOE using the amides we had been working on at QMC. This instrument proved to be the only one in over 30 years of NMR that was exclusively for my group. Thereafter I have always shared instruments with others (a Varian A-60, a Varian HR-100, a Bruker HFX-90, a Bruker WH-400, and now a Bruker AMX2-600 and a Sisco/Varian 200 Imager).

I was lucky on arrival at QMC in 1961 to find it was blessed with an expert NMR group in physics headed by Jack

Powles, which included Peter Mansfield and John Strange. I was grateful to Jack for access to one of his instruments which Derek Shaw used for ^{19}F work and gave us the first QMC NMR chemical paper in 1963.⁶ In the early 1960s I learned from them the utility of pulse methods and for the first time I came across Fourier transformation: the group took FTs of the CW wiggle beats in field-swept spectra of liquids. I was therefore fully alive to the possibilities for chemical work of the first commercial FT spectrometers. I obtained the first of these in the UK (a Bruker HFX-90) in 1969–70 for work mainly on ^{13}C (organometallics) and ^{15}N (amides and peptides), and we managed the first ^{15}N FT studies at natural abundance⁷ as well as the first $^2\text{H}\{^1\text{H}\}$ FT work on deuterium.⁸ It was a large grant (eventually worth about £90 000) but in return I had to run a national service!

I did not realize either the utility of the 'solid echo' which Jack's group popularized, until much later (in 1992!) when I used it in the stray field imaging technique at Bruker Spectrospin with Klaus Zick⁹ for the imaging of liquids in solids.

Since those times I have had a succession of very able colleagues at QMC, notably Paul Pregosin who took us from amides to peptides with FT in the 1970s and with whom I published a review on ^{13}C ,¹⁰ and then Geoff Hawkes who had fun with ^{15}N NOEs in peptides,¹¹ as well as with ^{13}C and ^{17}O in organometallics,¹² Paul Kinchesh and Steve Williams in the 1990s with direct and indirect imaging of ^{14}N and ^{15}N .^{3,4,13} There were enjoyable collaborations abroad: Luciano Milone and Silvio Aime at Turin on organometallics,¹² Filippo Conti in Rome on peptides,¹⁴ Rosanna Mondelli and Giovanni Fronza in Milan with heterocycles.¹⁵

Pieces of work which I enjoy looking back on and not mentioned above are: (i) the structure of pyrrole- ^{15}N from 'liquid crystal spectra' with Erkki Rahkama¹⁶ at an accuracy good enough for Jim Emsley to do some vibrational corrections;¹⁷ (ii) similar oriented work on the change of bond angles at nitrogen in 4-substituted anilines produced by the substituent (with the Milan group);¹⁸ (iii) the very beautiful treatment of double resonance spectra by Solveig Paget, which with the aid of Ruth Lynden-Bell and Alex Bain introduced the 'tilt effect' on intensities in d.r. spectra;¹⁹ (iv) the work of Derek Shaw on 'second order paramagnetics' (paramagnetics with no unpaired electrons);²⁰ (v) work with Jerry Zuckerman on Si–N systems (in which we introduced the very useful term 'isotopomers', which differ only in isotopic composition);²¹ (vi) the contributions to the study of lanthanide shift reagents;²² and (vii) work on NMR studies of ion pairing in solution.²³

My latest thoughts on the definition of double resonance in the epoch of time domain studies are in a brief review.²⁴

I am proud, at the suggestion of Jim Emsley and Kjeld Schaumborg, to have started the *European Experimental NMR* conference at Kent in 1974.²⁵

The moral I would offer to a chemist entering NMR is get with the latest instrumentation, your own or someone else's, find out what the physicists are doing, sniff out (or create) tomorrow's techniques, and *be lucky*, especially with your collaborators. Lastly, if someone tells you your experiment will not work, remember it is often easier to try it than to argue. I remember (non-NMR) colleagues questioning the utility of trying to measure ^{15}N spectra at natural abundance. Some are now doing the same for ^{15}N imaging! Always press on.

Raynes, W. T.: Early Work on Gas-Phase Chemical Shifts

W. T. Raynes

University of Sheffield, Sheffield, UK

Although few laboratories at the time had NMR instrumentation, many chemists were aware by 1959 that NMR was the coming thing in chemistry. It was in the same year that the famous monograph of Pople, Schneider, and Bernstein appeared. Theirs was not the first book on NMR but it was the first which made clear that the new technique would have manifold applications in chemistry. Indeed, so rapid were subsequent developments that by the mid-1960s the later chapters of the book were totally out of date.

The National Research Council of Canada had achieved world fame long before 1959, largely because of the research in ultraviolet spectroscopy carried out by G. Herzberg and his associates in the Pure Physics Division in Ottawa. However, from about 1956 the NMR work of H. J. Bernstein and W. G. Schneider in the Pure Chemistry Division had become very well known. In late November 1959, I arrived at the NRC Laboratories on Sussex Drive to take up a postdoctoral fellowship with Bernstein.

He suggested that I continue the work on solvent effects on chemical shifts in liquids that had been started by my predecessor R. J. Abraham who had left some weeks earlier. I first gained some knowledge of chemical shifts from Chapter 4 of Pople, Schneider, and Bernstein's book. It was clear that to measure solvent effects properly it was necessary to obtain the chemical shift of the solute in the gas phase. By February 1960, I had obtained a gas-phase proton signal from HCl at 20 atm pressure. Without realizing the implications, I thought that a result at a lower pressure would be more satisfactory. A 10-atm pressure sample gave a slightly different result. Bernstein immediately saw the importance of this and from then on most of my work involved gaseous samples.

Within a short time I obtained a density dependence of the proton chemical shift of HCl gas with a negative slope. This is now known to be a universal feature of nuclear shielding in the gas phase after correcting for bulk susceptibility. I went on to obtain linear density dependences for the proton resonances of CH₄, H₂S, and C₂H₆. In all these studies samples were at room temperature. At that time 'state-of-the-art' NMR spectrometers operated with field sweep at 60 MHz (or '60 megacycles per second', as one said). There was no lock, and drifting of the field frequently occurred. To allow for this it was the practice to record signals both for increasing and decreasing applied fields in quick succession through resonance. I learnt much about practical NMR from J. Nicholson who was the technician in charge of the Varian V-4300 B instrument with which the work was done.

A. D. Buckingham, who was in Ottawa during the summer of 1960, became very interested in our results. Within a short time he produced a theory of intermolecular effects on nuclear shielding in gases. This was based upon a virial expansion of shielding and incorporated the physical ideas of distinct van

der Waals, electric field, and magnetic anisotropy contributions which had been described shortly before.¹

The theory suggested that it would be profitable to study binary gas mixtures, i.e. the dependence of proton shielding in one gas on the density of a second, perturbing gas. I soon obtained results for a number of gas mixtures and found, with one exception, that they fitted the new theory very well. The exception was the HCl/CO₂ mixture. I suggested to Buckingham that the electric quadrupole moment of CO₂ could be important here. He then produced an extra term to account for this. An excellent fit of all results to the theory was then achieved. I wrote up the work in the summer of 1961 and it was published² in 1962. The paper has been cited frequently down the years and is often referred to as 'RBB' or the theory as 'the RBB theory'. It was in this paper that the coefficients *A* and *B*, often now used to describe the electric field dependence of shielding, first made their appearance. I left Ottawa in October 1961 and moved to Caltech to work in a different field with G. W. Robinson. During my period in Ottawa other significant NMR work was being done including the first study of substituent effects on carbon-13 shielding³ and the first measurement of a carbon-carbon spin-spin coupling constant.⁴

In late 1961 Buckingham published a note⁵ pointing out that an observed temperature dependence of chemical shifts could be attributed to the stretching of chemical bonds. He wrote the shielding in a diatomic molecule as a power series in the 'reduced' bond length. When I resumed gas-phase studies in the late 1960s, I used this idea with my research student, the late B. P. Chadburn, to determine the bond length dependences of the proton shielding in HCl and HBr from the observed temperature dependence of the proton shielding.^{6,7} This was the first use of the NMR technique, I believe, for measuring the dependence of a property on molecular geometry. Shortly after this I turned again to intermolecular effects in gases and, with K. Jackowski, obtained a density dependence of carbon-13 shielding⁸ and later with E. Dayan we studied carbon-13 shielding in binary gas mixtures.⁹

The RBB paper was not the first to report density-dependent shielding as Gordon and Dailey¹⁰ published their result for C₂H₄ first. After I left Ottawa, Bernstein continued gas-phase work with L. Petrakis, G. Govil, and S. Mohanty. There was soon a flourishing group in Paris.¹¹ Important work was also done by Rummens who wrote an early review of the subject.¹² However, since the mid-1970s the field has been dominated by C. J. Jameson. Together with A. K. Jameson and their co-workers, she has made many contributions to the two branches into which the subject is divided—intermolecular and intramolecular. She has also shown that isotope shifts can be accounted for by the same theory which deals with intramolecular effects. She has written the most recent review of the subject.¹³

There is still much work to be done!

Redfield, Alfred G.: Foundations and Structures

Alfred G. Redfield

Brandeis University, Waltham, MA, USA

The first NMR signal I ever observed was my most interesting one. It was not the result of careful planning, but a true discovery. Despite all kinds of influences, I had not intended to go into NMR until a few months before I found this signal, and I was pursuing relatively routine research at the time.

I come from a scientific tradition, founded by my great great grandfather, William C. Redfield ('C' was his entire middle name which he gave to himself, as he said, 'for Convenience'). He discovered that hurricanes were cyclonic in the 1820s,¹ but never knew what the Coriolis force was, or the rotating frame, or how they explained his discovery. During World War II, I spent winter and summer vacations from school in a research laboratory at Woods Hole, led by E. B. Wilson, where I worked directly with C. P. Slichter. The object of our lab was to record signals from underwater explosions.

In 1946, I entered Harvard where I kept in touch with Slichter, and had Purcell and Pound among my teachers. Slichter recruited me to go to graduate school at Illinois in 1950, and was very helpful to me when I got there, but I did not do my Ph.D. thesis with him because I foolishly thought that it would not be good to work directly for a friend. I worked for the first year at the Illinois betatron, but decided that big science was not for me. (I think times have changed, and NMR is now big science!) However, I took the data for my thesis (on the Hall effect in photoconductors) in Slichter's lab, borrowing the field of an electromagnet built by R. E. Norberg.

For my postdoc, I got an NSF fellowship to work with Harvey Brooks at Harvard. I did not yet realize that I had no talent as a mathematical physicist and it was fortunate that, when I arrived in September 1953, Brooks felt too busy to deal with me and suggested that I work with Nicolaas Bloembergen instead. Bloembergen had just returned from a trip to Japan and suggested I look into some mysterious nonmagnetic resonances observed in a solid by someone there. I had already picked out the vacuum tube to use to repeat these measurements, when I fortunately saw a book about piezoelectricity and recognized that these were piezoresonances.

His next suggestion was to measure T_1 in aluminum and copper, to help verify the prediction by Korringa that T_1 should be inversely proportional to temperature, and be related approximately to the Knight shift. Nico told me to do this using the saturation method with a crossed coil, rather than spin echoes which were then being used by Slichter and his co-workers in alkali metals. Saturation was a better method for aluminum and copper, which did not have the motionally narrowed lines of the alkali metals being studied at Illinois. Furthermore, no one in the lab had experience with the fast recovery pulse methods then being worked out by Slichter, Norberg, Hahn, and Lowe. It was a fortunate accident that Nico had me build a crossed-coil system (it was the first crossed-coil system built on the East Coast) because, not only is it

suitable for high CW power, but the noise from vibration is in the absorption mode rather than the dispersion mode of the signal. This was unexpectedly useful because the most obvious anomaly that led to the spin-temperature treatment² was in the dispersion mode.

Carson Jeffries kindly sent Nico the design for his spectrometer, which I recognized as the same kind of circuitry familiar to me from my days as an engineer at the Harvard radio station. My version (Figure 1) had six ganged air capacitors driven by a motor and gears to keep the rf stages in tune; I got this idea from my days at Woods Hole where my first job was to wire a master control panel that had several rotary switches ganged together in the same way. Of course, all radio receivers in those days used ganged capacitors. It was the tradition at Harvard to vary the frequency rather than the field, since everyone there tended to use the 'Pound box' marginal oscillator whose frequency could easily be varied. I first set up my system by looking at the sodium resonances in aqueous NaCl. Ted Rowland, who was Nico's first graduate student, working on quadrupolar effects and electron-coupled spin-spin interactions in metals, taught me how to prepare the copper and aluminum samples, and I was ready to go.

Sometime around the end of 1953, I looked at my first true signal in, probably, aluminum. It was easy to find the dispersion signal and I then rephased the system to get the absorption mode. Varying the power, I found that the absorption mode did saturate at fairly low power as predicted by Bloch's equations and Korringa's paper. But the rf level seemed lower than that at which I first saw a dispersion signal, so I rechecked and found that indeed the dispersion signal did not seem to saturate; I later found that the resonance also became narrower and more Lorentzian-looking. Subsequently, I verified this result in copper. Both Bloch's equations and

Figure 1 A. G. Redfield with the equipment used to make the observations that led to the hypothesis of spin temperature in the rotating frame. The original observations were obtained with a permanent magnet having a field of 0.3 T, instead of the Varian magnet shown here. All of the RF components are in the two boxes, mounted at an angle so that the cabling to the probe was short. This was done because there were no matched transmission lines, the tube plate or grid forming part of the tuned circuit. At the bottoms of these boxes is the motor and right-angle drive used to turn the six tuning capacitors in the boxes in synchrony.

an argument based on spin temperature in the fixed frame of reference given in Bloembergen's thesis predicted that absorption and dispersion should saturate together, so my observation was in at least 10-fold disagreement with theory and, therefore, worth thinking about. I did not understand this key phenomenon until around June 1954, six months later, as a result of lots of spare-time reading and thought. In the meantime, I improved the equipment for low temperatures and took more saturation data.

It may seem to the modern reader that my eventual explanation in terms of rotating-frame thermodynamics should have been trivial and obvious. In fact, other physicists observed the same thing at that time without being able to explain it. Finding an explanation required several steps. The rotating frame had been described with clarity by Ramsey and Schwinger, and Van Vleck's truncation of the dipolar interaction was well known to everyone. But it was not immediately obvious to me that the truncated Hamiltonian contained the terms which were rotation-invariant and were the secular terms I would have to keep in any rotating-frame theory. I also had to teach myself about the density matrix. This was not part of the standard training of physics graduate students in those days. The formalism was introduced to NMR by R. K. Wangsness, working with Bloch, but I learned of it in a talk by J. M. Luttinger on the ferromagnetic Hall effect in which he referred to the density matrix as an obscure method, and then I taught myself about it from Tolman's classic book.

Another step that I made on the way to fully understanding my observation was to realize that it could be explained by assuming that relaxation along the effective field was much slower than the normal solid state T_2 of a few microseconds. I named this relaxation time $T_{1\rho}$. However, it was not obvious how to connect this hypothesis to the idea of spin temperature.

Spin temperature was introduced in the 1930s in connection with electron spins at low temperature by Casimir and DuPre, and first mentioned for NMR by Purcell and Pound in their famous paper on negative spin temperature. I learned about it from a 1937 paper by Van Vleck, and I was always of the school that believed in the predictions of thermodynamics (in the fixed frame) for systems of tightly-coupled spins. A second school, whose most eminent member was Abragam, believed that this was not obvious because the nuclear spins were not in contact with a lattice containing many degrees of freedom (I hope I am presenting their view correctly). At about that time, unknown to me, Abragam and Proctor were working on their famous experiments to test the predictions of spin-temperature theory quantitatively. The views of this latter school were encouraged perhaps by the existence of theorists, notably Felix Bloch, who did not believe in spin-temperature predictions at all. The hardest pill for these physicists to swallow was the idea that nuclear spins would remagnetize themselves (for experiments done in a time short compared to T_1) after being adiabatically demagnetized. I recall a meeting around 1956 when Abragam presented his results. That evening I witnessed an animated discussion between him and Bloch which concluded with the friendly advice: 'Well, Anatole, you'd better think about it'. When I presented my plans to study relaxation of demagnetized spins at a meeting in Stanford, Bloch's comment was: 'Well, the spins have to be mighty smart to do that' (i.e. to adiabatically remagnetize themselves).

After months of scribbling pictures of spins flipping each other, and also having them do so in my head, I figured it out. It was not a gradual process: I can remember the exact stretch of road where, during one of my habitual night walks around Woods Hole, the phrase 'canonical distribution in the rotating frame' slipped into my mind. The better description 'spin temperature in the rotating frame' was probably coined by Abragam, some time later. In fact, before I got to this point, I reinvented temperature by asking what would happen to the energy (actually the 'effective energy', as described in the original paper) if a Bloch decay were to occur along the effective field. I provided a very general argument, based on conservation of this energy, that the entropy of the spins would decrease for a complete decay, violating the second law of thermodynamics.

In a few days, I wrote out a summary of the theory and presented it to Bloembergen, who was interested as well as perhaps a little skeptical about my ideas. Three days later, without much discussion, he agreed that my theory was probably correct.

The paper I eventually published in 1955 was too long, and the last section was a disconnected presentation on 'rotary saturation'. This was a CW method for investigating NMR with an audiofrequency field in the rotating frame. Here I found accidentally that the double resonance linewidth was relatively narrow when the effective field was oriented away from the z axis by the magic angle. I gave a correct explanation of this phenomenon, which was kindly mentioned by John Waugh in his papers on development of high-resolution NMR in solids; but I forgot to mention, in my paper that Bloembergen (who graciously declined to co-author my paper) pointed out the explanation of this important phenomenon in terms of an equation I had written but had not looked at carefully, truncating the dipolar interaction in a sort of double Van Vleck method. Later this narrowing was thoroughly investigated by Lee and Goldburg.

Before leaving Harvard, I completed work on a simple low-temperature set-up and measured T_1 of aluminum and copper as requested by Nico, below 4.2 K as well as at room temperature, verifying Korringa's theory (Figure 1). I did this by adiabatic rapid passage thereby demonstrating at least qualitatively a key prediction of my theory, namely adiabatic demagnetization and remagnetization in a spin locked state. This hasty experiment was the first example of intentional spin locking. I say 'intentional' because the original NMR signal seen by Bloch's group in liquids was apparently a similar adiabatic fast passage signal and the 'locking' was against decay due to static field inhomogeneity.

I felt at the time that all this was nice work, and doubted that I would ever do better; this has turned out to be true. I was surprised at how slowly my ideas were accepted and it was not until after Abragam's outstanding book was published that the theory became widely known, if not understood. He gave my paper an excellent treatment, which I appreciated, but I do not agree that my first paper was particularly obscure as seems to be widely believed. I did not have the advantage of three years of other experiments on fixed-frame spin thermodynamics to describe, by way of introduction. My main task was to explain the unexpected observations I had made and these were not easy to connect with the rather simple idea that I eventually proposed. In fact, I suggest that the reader go back and read my 1955 paper.

In 1955, I moved to the IBM Watson Laboratory at Columbia University, and I decided to concentrate on properties of superconductors rather than do more on pure spin theory. I will come back to Harvard and the Watson lab later, and continue with further aspects of spin temperature now.

Within a few years there were tests of the predictions of my theory for spin systems containing only one species of spin by Donald Holcomb and by Walter Goldburg (whose interesting early contributions to this field are not fully recognized). In the meantime, there was widespread investigation of variants of the Overhauser effect, first observed by Carver and Slichter, driven to a considerable degree by interest in the development of polarized targets for particle physics, culminating in the development by Abragam's group, and independently by Jeffries' group, of the solid effect. Hahn continued to perform pulsed double resonance NMR experiments in solids in an obsessive search for ways to observe rare spins using abundant ones as detectors. Possible connections between all these activities were not obvious, at least to me, even though I had almost accidentally included a treatment of what would happen if a second species of spin were present for single resonance in my 1955 paper. I did this because copper has two naturally abundant isotopes.

In 1960, Abragam kindly welcomed me for a sabbatical year's stay at Saclay. When I arrived he asked if I would like to be called 'Al', and then informed me that I could call him 'Anatole', but it would not be a good idea to shorten it to 'An' (non French speakers can consult a dictionary). I spent the year working with André Landesman on a long-shot experiment to polarize helium-3. The experiment did not work, but it was fun trying it. Abragam's book was in press during that year, and it is interesting to reread his treatment of my theory and then to read his sections about two experiments to which it might have been applied, namely the solid effect (which might now be described as Hartmann-Hahn cross polarization, except for minor details), and the first observation of polarization transfer between two nuclear species by Sorokin and Bloembergen. Abragam did not clearly make the connection, and despite the general interest in spin-transfer experiments at the time, engendered by the various nuclear polarization methods, we were not good at extending these ideas to cross polarization.

Among the first papers to describe two-spin-species experiments coherently using spin-temperature theory were those of Landesman and Goldman, discussed elsewhere in this volume by Goldman (see *Goldman, Maurice: The Time when Spin Temperature was Hot Stuff*), and of Hartmann and Hahn, which appeared as an abstract during my year at Saclay. The famous Hartmann-Hahn cross polarization condition did not come as much of a surprise to us, and I thought the really nice feature of their experiment was their method of draining spin order from the abundant protons by phase reversing the rare spin rf fields. This idea has been nearly forgotten by modern solid state NMR spectroscopists. The second important contribution of Hartmann and Hahn was to use very strong rf fields, several times the dipolar field, for cross polarization. Doing so allows one to neglect various aspects of the spin-spin interaction that are dear to my heart but that most people do not want to know about, and more importantly it leads to efficient polarization transfer. On the other hand, Landesman and Goldman showed that a somewhat greater polarization transfer can be achieved by using a weaker rf field and slightly violating the Hartmann-Hahn condition.

On returning from France, I immediately performed a field cycling pure quadrupole resonance version of the Hartmann-Hahn experiment (borrowing also some ideas from the Landesman-Goldman work), as did several others. I was pleased with this work because it related to the thesis of Ted Rowland who helped me a lot during my stay at Harvard. Magnetic field cycling resonance in zero field has also been used by A. G. Anderson to verify the predictions in the classic papers by Van Vleck on low-field lineshapes, essentially repeating for nuclear spins the 1930s experiments by Gorter on electron spin systems.

A few months later, I received the paper of Landesman and Goldman from the *Physical Review* to referee. On the referee form, typed in red, was the question: 'Is this paper too long?' I read the paper, and said it was too long and should be shortened (almost always good advice). I have forgotten what else I said, but before long I saw the article appear in *Physical Review* with the acknowledgement of the minor help I had given while I was at Saclay [described by Goldman in this volume (see *Goldman, Maurice: The Time when Spin Temperature was Hot Stuff*)]. The following summer at the Gordon Conference, we heard Slichter describe some experiments related to the rotating frame. Abragam always came to these conferences, sitting in the front row in a leather chair that seemed to be reserved for him, and we awaited his comments on each paper with great interest. This time, after complimenting Slichter on his talk, he said (paraphrasing): 'Two years ago [at the previous Gordon Conference], I described some nice work by Landesman and Goldman ... At that time, I had the impression that no one understood me. Recently we sent it to *Physical Review*, and the referee, I don't know who it was ... [looking about the room for effect] didn't understand it either.' I managed to keep a straight face; of course, there could have been another referee.

To further illustrate some confusion at that time, I will mention some other papers. One was by Goldburg, who ingeniously studied the expected cross saturation of spectral lines which due to quadrupolar splitting could be moved about to overlap or not, by rotating a crystal. The lines did not crossrelax as expected and neither Goldburg, nor I, could explain this, although in my heart I knew that I should be able to. Jean Jeener eventually did so using spin-temperature arguments in a way that seems completely self-evident in retrospect. The same kind of reasoning was later used by Azriel Genack and myself, and by Stengers and Jeener (unpublished), to predict that spin diffusion would be quenched in the presence of large gradients in the static field. Even if one step of cross relaxation or spin diffusion is possible kinetically, because spectral lines may overlap slightly, nevertheless energy is not conserved in the long run by cross relaxation. In the case of spin diffusion in rigid solids (not applicable to proteins!), we deduced a two-component diffusion equation which seems unique in transport theory.

During this period my student, Peter Solomon, investigated cross relaxation between electron spin multiplet lines, and proposed several mechanisms to explain why the peculiar phenomena mentioned above are not seen in these systems. I developed a moment-method expression for spin diffusion in solids and, with William Yu, applied it to estimate the spin diffusion coefficient in solid helium. Herman Bleich and I developed a double resonance method, combining Hartmann-Hahn cross polarization with decoupling, which we

called ‘higher resonance NMR in solids’ (I did not have the courage to call it high resolution). Bleich and C. S. Yannoni³ used this method to measure the chemical shift anisotropy in benzene, scooping Pines, Gibby, and Waugh by six months. However, the method was too awkward to compete with their straightforward scheme, and was forgotten. Regretably, the obvious acronym for their method is not approved for this Encyclopedia.

The impact of this work on other fields has not been great, other than its relevance to nuclear polarization and solid state NMR in general. However, R. V. Pound recently pointed out to me that the energetics of trapping of free ions and molecules by rf fields is strongly analogous to phenomena like adiabatic demagnetization of spins in the rotating frame.

I will not say much more about spin-temperature physics, since Goldman has said much about it in this volume including a description of the fascinating ultralow temperature states he and his collaborators have studied (see *Goldman, Maurice: The Time when Spin Temperature was Hot Stuff*). He says correctly that spin-temperature theory has declined in general interest. I will mention one other reason why the theory is not well known any more. Starting with experiments like those of Hartmann and Hahn, and including the developments by Waugh’s group and also the related HOHAHA or TOCSY methods in solution, you do not need this added theory to understand the dominant trick. It is Hartmann–Hahn cross polarization transfer via mutual spin flips that conserves energy or polarization in the rotating frame at high effective field. It is plausible that this process will occur as long as you forget that Bloch would have expected the transverse magnetization to decay in a short time. The fact that it does not was also a problem for electron spin systems at low static fields in the experiments of the 1930s. It is permissible to forget these things for simple processes with good Hartmann–Hahn matching. Only when overall energy is not conserved for a mutual spin flip, as in the Goldburg experiment, will you get unexpected results.

Now I will go back in time, to my postdoc days in Bloembergen’s group. In developing the spin-temperature theory, I had to make assumptions about spin–lattice relaxation in order to estimate the steady-state spin temperature. Relaxation of the Zeeman part of the rotating frame energy was straightforward, and I assumed double that rate for the spin–spin part of the energy. My reasoning was that each of two interacting spin partners would relax independently at the single-spin rate. I felt that this could not be exactly true since these spins were close together, at a distance comparable to the electron’s wavelength. I think this was why I got interested in relaxation theory on a deeper level. It turns out that the correction implied by what I just described is rather small. Furthermore, Hebel and Slichter later provided an elegant sum-rule to calculate the same correction in their famous papers on relaxation in superconductors. Another stimulus was a lecture I heard by Ioniel Solomon, who was then a visitor in Purcell’s lab, doing his famous study of two-spin (hydrogen fluoride) interaction and relaxation. He described transverse relaxation somewhat by analogy to longitudinal relaxation in the presence of a small imagined transverse circularly polarized rf field.⁴ I thought that he was really using a density matrix in disguise and that I might do better by explicitly using it.

As mentioned above, Wangsness and Bloch had just published their paper on the quantum theory of relaxation of

a spin- $\frac{1}{2}$ nucleus, and I also had access to a preprint of Kubo and Tomita’s paper but I could not understand either one. So I asked Bloembergen where he got the theory involving spectral densities outlined in his paper (‘BPP’, with Pound and Purcell) and he referred me to a paper by Pound and Abragam and the review by Wang and Unlenbeck. I had absolutely no other knowledge of correlation functions and noise theory. For quantum theory I just used the notes of the excellent introductory quantum course I had at Illinois, taught by James Snyder, which I audited in my second year there after taking it in my first. I think the first thing I did was to derive T_2 quantum mechanically using the same math as is used to derive ‘Fermi’s golden rule’, relating the transition probability to the density of final states and the square of a connecting matrix element.

At about this point I mentioned to Bloembergen that I had done something like this; at the time I did not think it to be worth much because of the other work on relaxation. He urged me to write a paper, so I began to work harder on it and eventually to solve the problem of spin–lattice relaxation of spin–spin energy that got me started. The developments I just described must have occurred during 1954–55, and I did not complete the article until after I left Harvard.² I was persuaded to publish it in the newly founded *IBM Journal of Research and Development*, a poor choice. It would have died there but for the fact that Solomon and Bloembergen used it in their famous papers and that Slichter described it (appropriately coupled with the names of Wangsness and Bloch) in his book.

When I am introduced for talks these days people speak uneasily about ‘my’ relaxation theory, and mention none of my older work. Actually I feel ambivalent about relaxation theory for a variety of reasons, in addition to the many precursor theories which I already described. I never considered myself a true statistical physicist, and the feeling is no doubt reciprocated by such physicists. Much the same theory was worked out by Bloch and co-workers at the same time, while he was Director of CERN (the joint European high energy physics laboratory). I did not really know what I was doing and certainly did not realize that spin relaxation is in virtual one-to-one correspondence with Brownian motion theory, being the result of Brownian motion in Hilbert space. I also missed the second-order shifts produced by fluctuating perturbations, discussed in another volume of this Encyclopedia by Werbelow (*Dynamic Frequency Shift*). The theory itself is really a straightforward extension to quantum systems of old classical ideas, and the discussions in my paper justifying my methods are nothing more than justifications of perturbation theory. My ambivalence was similar to that of Abragam when he contemplated developing relaxation theory at about the same time, as described in his autobiography. Eventually, of course, he did so in his treatise, emphasizing an operator formalism. Both formalisms are useful for different kinds of problems.

My treatment did have a few unique features. Even though people complain about its complexity, it probably remains the simplest complete paper on the subject for readers who are not specialists in quantum physics. This was mainly a consequence of my amateur status as a quantum physicist. My notation was excruciatingly cumbersome for some problems but was suited for chemical problems; this was a consequence of my interaction with Solomon. It was the first theory to include partially correlated fluctuations. It is perhaps the only paper to explicitly treat relaxation both

classically and quantum mechanically. It contains a section on interaction with the measuring device which no one, to my knowledge, has read. Finally, the paper introduced the idea that transverse relaxation may always exist between off-diagonal density matrix elements, but is ineffective unless they nearly overlap in frequency. I don't think I conceived that such transverse-transverse relaxation could be observed in experiments like CAMELSPIN-ROESY⁵ until somewhat later. My only subsequent work in this area was to spend almost the entire summer of 1963 calculating a single correlation function for relaxation in NaCl due to vacancy diffusion, with Maurice Eisenstadt.

Private compliments were paid by Bloch who telephoned me in late 1955 after briefly meeting me and I suppose receiving a preliminary manuscript, to ask me to collaborate; I said, 'no thanks'. Later, probably after I completed the paper and sent it to him, his postdoc Bernard Herzog reported (via my co-worker Richard Blume) that Bloch said to him something like, 'say Bernie, this Redfield . . . he's Jewish, isn't he?' The papers Bloch wrote at that time are probably the first ones on the rf field dependence of $T_{1\rho}$ which I did not treat at all.

During my second year at Harvard, Bloembergen encouraged me to repeat Knight's early experiments on colloidal superconducting mercury. I had a good second-hand feeling for both superconductivity and low-temperature physics from observing my friends at Illinois, and was happy to do so. The only thing that came out of this was the low temperature measurement of T_1 in aluminum and copper that I mentioned earlier; someone tried to make a colloidal mercury sample for me, but was unsuccessful.

This work was cut short in 1955 because Bloembergen recommended me to IBM to take over Erwin Hahn's lab. I visited the IBM Watson Laboratory, meeting Hahn for the first time, and shortly I received and eventually accepted their offer. Meanwhile, I was sharing a lab with a student who was trying to duplicate the Purcell, Pound, and Ramsey experiments to study phenomena at low and zero field by moving a crystal from a high magnetic field to a low one and back. All these things led me to think of measuring T_1 in superconductors in the same way. This was a somewhat risky experiment because it was not clear that the spin polarization would survive the rapid changes in field as the metal went superconducting and back.

Over Christmas in that year I stopped in Illinois on my way to ski in Colorado, and naturally dropped in to Slichter's lab. There I learned in a casual conversation with his students that he had exactly the same idea and that they were working on it. Slichter encouraged me to try it anyway, and told me that we should not discuss our plans further until one of us had some results. However, I didn't have time to start this experiment until I got to my new job at IBM in September 1955. As I expected, I received a letter a few months after arriving there from Charles Hebel, Slichter's student, announcing success and describing the completely unexpected rise in relaxation rate just below T_c in aluminum. Of course I was envious, not because I was scooped but because it must have been truly exciting to make this discovery next to Bardeen, Cooper, and Schrieffer as they finally solved one of the great mysteries of the century. However, had I been in Slichter's shoes I doubt if I would have been smart enough to work out the details of NMR relaxation in the same way that he did. It did not work out so badly for me, because it was of course desirable

to check the Hebel-Slichter result and eventually to extend it to a wider temperature range, which was achieved by Arthur Anderson and Yoshika Masuda in my lab.

The IBM Watson Laboratory at Columbia University was my home for the next 15 years. It was a remarkable place and deserves a description for several reasons, including the fact that it housed several distinguished workers in NMR: Hahn, Martin Karplus, Richard Garwin, and Seymour Koenig, as well as others who worked on EPR in biological systems. It was the first more-or-less 'pure', or relatively undirected, research lab in IBM.⁶ Most of its senior researchers had adjunct positions in various departments at Columbia University, which was half a block away. It was a small lab, occupying a town house and a nine-storey converted apartment house, and having about 10 research groups. Eight members of the lab eventually became members of the US National Academy of Sciences. One reason Hahn was hired was that it was possible to store information in stimulated spin echoes.⁷ By the time he left for Berkeley it became obvious that this idea was not promising; less than 1000 bits of information could be stored in a magnet weighing 100 lb or more, and the pulses came out in time-reverse from the order they were read in.

I was, of course, highly honored and also lucky to succeed Hahn. I inherited a very early Varian magnet and two long-term co-workers: William Kiselewsky, who was still helping Seymour Koenig and Rodney Brown construct NMR relaxivity machines at IBM until shortly before his death in 1993, and Richard Blume, who observed the first electron spin echoes. A student inherited from Hahn, George Whitfield, performed probably the first NMR experiment in a rotating rf field before he became a theorist; his work was extended by Richard Hecht. Another inherited student was Arthur Anderson, who got the superconductivity experiment going, and eventually rose to be Director of Research and then Vice President of IBM. Right next door were Richard Garwin and Haskell Reich, who were doing the earliest experiments on liquid and solid helium-3. It was entertaining to have Garwin as a neighbor; he is probably the smartest individual I know, having been involved in a wide range of government and IBM consulting jobs as well as physics. Early in my stay, I returned from a trip to be informed by Dick Blume that he had with great difficulty prevented Garwin from making off with one of my low-field Helmholtz coils. It turned out that this would have been used for the discovery of parity violation in which Garwin participated. Another colleague, L. H. Thomas, almost discovered the fast Fourier transform (FFT) in the 1940s when theorists used mechanical hand calculators, but he did not tell anyone about it.⁸

Masuda and I built a magnetic cooling apparatus and then a helium-3 pumped system and carried the measurement of T_1 in superconductors to 0.2 K. I spent most of the rest of my time at Watson Laboratory applying field cycling NMR⁹ to superconductors with the help of Warner Fite, Albert Kung, and Azriel Genack. I showed that the vortex structure in type II superconducting vanadium was triangular, based on the NMR lineshape. I proudly presented this work at the Low Temperature Meeting in Moscow to the many Russians and others who were responsible for so many developments in superconductivity. During that meeting Slichter and I arranged to meet B. N. Provotorov, who kindly invited us to his institute to meet some of his associates. The field cycling circuit that we built was later taken over by Seymour Koenig and Rodney

Brown, who developed it extensively for the study of various problems in protein structure and dynamics, and magnetic resonance imaging.

In the 1960s a biophysics program was started at the Watson Laboratory by R. L. Garwin, who had become Director of the laboratory, and continued by S. H. Koenig, its third Director. Phillip Aisen, a biochemist who used EPR to study metalloproteins, joined the lab. I was encouraged by them, and by a talk I heard by Melvin Klein at a meeting in 1968, to try FT NMR in proteins. The promise of NMR in biochemistry had already been demonstrated by Oleg Jardetsky, Robert Shulman, William Phillips, Mildred Cohn and others, but there were no FT machines available commercially. Ernst's paper had appeared, and two homemade FT machines were under construction by Klein and by Hyam Sternlicht. By the fall of 1968, I had decided to build a proton machine with quadrature detection, soft pulses for water suppression, and a pulse programmer that could control presaturation. I think I thought these things up on my own, possibly influenced by a 1964 paper by W. G. Clark which showed the properties of quadrature detectors feeding 'box-car' integrators. However, I soon learned that Schlom Alexander had already invented the soft pulse in Saul Mieboom's group at Bell Labs, and much later I learned that Richard Ernst had submitted a patent on the quadrature detector in 1968. Jeener told me how to build the timing system based on a single present counter.

I was not sure whether quad detection or soft pulses would work, or what we would study with our instrument except that we would look for saturation transfer in a protein. My main motivation in using quad detection was to reduce the required transmitter power and be able to work on one side of the water resonance with a soft pulse to eliminate the water signal. I knew that the quad detector would improve the signal-to-noise ratio, but I forgot to say so in our first paper. We paid \$40 000 for a demonstration 100 MHz JEOL CW spectrometer, and the first thing I did while waiting for it to be delivered was to build the quad detector and filter system. The spectrometer came in the spring and Raj Gupta joined me in furiously building the pulsed modifications and programming a computer.

In the middle of this we learned that the Watson Lab would close soon, but we could not think of anything else to do but to continue. The spectrometer in the basement transmitted data at the end of each run to a computer on the 7th floor, and was controlled in part by a mechanical cam timer and a telephone stepper relay. We would then run up to this computer, which belonged to another project, and would take the 512 punched cards that it produced to a larger computer which could do the FT. Data transmission occasionally dropped a bit and if so Gupta would find the card having the bad bit and manually replace it with one encoding the average of the two adjacent data points. Despite these problems we got our first FT spectrum in the fall. This was the first FT instrument to be used for proton and protein NMR research.

Gupta wisely chose to work on cytochrome-*c*, which had already been studied using CW NMR by Wüthrich and Shulman, and by W. D. Phillips. We soon got acceptable spectra even though we were working at 100 MHz whereas Shulman and Phillips had 220 MHz Varian spectrometers. As suggested by an early paper by Arthur Kowalsky, pointed out to us by Thomas Fabry, we connected assignments of the oxidized and reduced heme methyl resonances using saturation transfer. This permitted an estimate of the electron-transfer

rate, and shortly afterwards Gupta found our first NOE. These were the first observations of these effects by FT NMR and in a protein.¹⁰ In the spring of 1970, I reported our machine architecture and spectra at the Experimental NMR Conference, but I did not report the electron exchange results that we obtained a week before since I assumed, erroneously, that others might easily be able to do this experiment. However, I could barely prevent myself from talking about them. These saturation transfer results connected key assignments made separately by Wüthrich, Shulman, and Phillips in the two states of cytochrome-*c*, thereby solidly confirming these results and showing that a methionine was coordinated to the heme in both states. R. E. Dickerson kindly permitted us to visit his lab and view his oxidized-state crystal model. There we learned that his preliminary (never published) reduced-state structure was wrong with respect to the heme coordination, and we told him so. After some delay, he fortunately corrected it before publication.

I spent the following two years in the lab of D. E. Koshland learning biochemistry. Commercial FT instruments appeared around 1971, but they were really inferior to the one we built except for the computers. The engineering level in these instruments remained disappointing until the mid-1980s.

In 1972, I was fortunate to move to Brandeis and we ordered the second Bruker WH-90 to be sold in the US. Meanwhile, I hired Sara Kunz, a recent Brandeis physics major, and we started building a front end for our own system, again starting with the quadrature detector. The WH-90 arrived in the summer of 1973, and as we had planned we used it as a test instrument for our own electronics. Bruker thought they had a good instrument, but we knew better; for one thing it had no quad detector and could not cope with the H₂O solvent problem. Even before final acceptance they were startled to find wires issuing from the back of the instrument leading over to our unprofessional-looking relay rack. This instrument now has a 500 MHz magnet and most of it has been replaced over the years. It probably holds the world's record for length of service.

As I had at IBM, during my decades at Brandeis I tried to maintain a high level of problem-oriented research and spent only a fraction of my time on technical matters. I won't review these years except to note one striking change: the developments in high-resolution NMR which we demonstrated around 1972, namely the use of soft (later composite) pulses to suppress water, and quadrature detection, were not used by anyone else until about five years after I first presented them. I really could not understand why, since they were really easy to implement and obviously useful. The same can be said of 2D FT NMR, invented at the same time. That idea was more complicated to develop, but was much more significant.

In contrast to this period of slow acceptance of new ideas, the pace has increased dramatically over the last 10 years. New methods are seized immediately and developed or used right away. Most likely this is because a lot more smart young people are entering the field or have entered it and are training other talented students; and because NMR has shown itself to be an extremely useful and generally accessible technique in biology.

Although my talent and most important contributions to NMR probably lie in the area of technical development, I am happy that I did all the problem-oriented work that I have hardly described here. It has enabled me to be a

spectator, and in a very minor way a participant, in fields that were developing rapidly and dramatically: superconductivity, biosynthesis of proteins, and the early stage of the part of biological development which is called signal transduction. At the same time, I treasure my contacts with the early giants of magnetic resonance: Gorter, Van Vleck, Purcell, and Bloch, as well as my friendship with the next generation of workers, such as Slichter, Bloembergen, Hahn, and Abragam, continuing all the way to the current group of very talented and dedicated young pulsed NMR jockeys.

Reeves, Leonard W.: Early Application of NMR to Chemistry at the National Research Council of Canada

Leonard W. Reeves

University of Waterloo, Waterloo, Ontario, Canada

The National Research Council of Canada with laboratories in the capital city of Ottawa was financed directly by the Government of Canada and after World War II came under the directorship of the Canadian scientist E. W. R. Steacie. With much vision and considerable determination, Steacie organized the overall research council into pure science and applied science divisions. Steacie set up a series of competitive postdoctoral fellowships to fill up the funds allocated and provide continuous renewal of ideas. Rapidly after World War II, the laboratories gained international respect in several fields.

W. G. Schneider and H. J. Bernstein were among the permanent scientific staff of the Pure Chemistry Division, and they had combined their capital budgets to purchase an NMR spectrometer from Varian Associates in California. In those early days there were two spectrometers in Canada; the other had been delivered to the University of British Columbia at the request of Cyril (Chris) Reid. I was awarded a postdoctoral fellowship to join the research efforts of W. G. (Bill) Schneider in 1956. When I arrived, the NMR 40 Mc/s spectrometer had been in operation for less than one year. I was offered problems either on ultrasonic relaxation or on the new NMR equipment, and I chose the latter. The original 30 Mc/s equipment of Varian had been upgraded to 40 Mc/s and was only useful for the observation of proton and fluorine magnetic resonance in liquids. While it would be wrong to underestimate the contribution of Varian Associates to the application of the technique to chemistry, there were defects in the equipment as sold at that time. A drawback was the reproducibility of the sawtooth field sweep. The line voltage affected the magnetic field drift, and it was an advantage to work in the evening when the line voltage was more stable. When I arrived in Ottawa, the activities on the spectrometer were suspended while the laboratory awaited the arrival from Varian of the so-called superstabilizer. This device was a sensor of field drift using large search coils set in place on the pole caps of the main magnet. The induced currents from field drift were fed to a galvanometer, and neutralizing currents were fed to buck-out coils in the same assembly, thus stabilizing the magnetic field. If properly used, the superstabilizer almost eliminated the long term drifts. The device was also used to sweep the field slowly, and a slower recorder could be used to approach the slow passage conditions set out by Bloch in his description of resonance.¹

The philosophy of the laboratory at the time was to try to seek out problems which would illustrate for all time how useful NMR might be in chemistry.

By the summer of 1956, the range of chemical shifts of the proton magnetic resonance in chemical compounds was

already known to be about 15 ppm. Those resonances found at lower field were considered to be deshielded with respect to those which appeared at higher magnetic field. The chemical shifts were laboriously measured and calibrated using audio sidebands impressed upon the field sweep coils. The matter of finding a standard chemical shift signal which would serve for referencing all proton signals was discussed at length among members of the group. The signal from cyclohexane was initially used but did not survive because it was not sufficiently separated from other aliphatic-type protons. The cyclohexane peak also suffered line broadening at temperatures below room temperature because of the slowing of the chair-to-chair conversion rate.

Schneider and Bernstein had funds available to invite visiting senior scientists, and we had the pleasure of the addition of John Pople, then with the National Physical Laboratory in England. I was present at many of the afternoon informal seminars though I was myself a student rather than a speaker. The decision to write a book on the subject of high-resolution nuclear magnetic resonance followed.² The puzzle of the time was the unusual position of the signal from protons on benzene in the range of chemical shifts of protons. John Pople realized that the large diamagnetic susceptibility anisotropy of the benzene π -electron system was responsible for the anomaly. On one of his trips to Ottawa, he used the time during the trans-Atlantic flight to write a note to the literature showing the correct order of magnitude and direction of the effect.³ Bill Schneider pursued studies on solvent effects, and there was an immediate application of the large diamagnetic susceptibility of benzene in solvent effects using benzene solutions.⁴

Another subject was the fact that the changes in hydrogen bonding in a solution produced large changes in the chemical shift of the hydrogen-bonded proton. Unfortunately, the lifetime of an individual hydrogen bond is too short to resolve individual peaks of different hydrogen bonded configurations. In benzene solutions there is a weak tendency for hydrogen bonds to form between the π -electron system and a hydrogen-bonding species. In my own experimental work, it became clear that chloroform molecules did form a weak hydrogen bond with benzene, and the large diamagnetic anisotropy of benzene was a special way to illustrate this using proton magnetic resonance.⁴

There was a need for a broad selection of proton resonance spectra in order to present the fundamentals of spectral analysis, where the chemical shifts were not large with respect to the so-called scalar spin-spin coupling between the nuclei to include in the proposed book. After much discussion, the type of nuclear system was classified according to the upper case letters of the alphabet. Two protons which were not chemically shifted became denoted as A_2 ; those with a small chemical shift and tight coupling were denoted as an 'AB'-type spectrum. As the chemical shift increased in relation to the nuclear spin coupling, the upper case letters were further removed in the alphabetic sequence. This simple notation immediately gives a notion of the complexity of the matrix to be diagonalized in the calculation of theoretical spectra.⁵ Pople used the occasion to make full use of symmetry in the choice of nuclear spin functions for the calculations, and this simplifies the overall diagonalization procedure as well as eliminating many spectral transitions.⁵ The original notation of Pople has been greatly extended since these early studies,

but the framework of the notation survives up until the present time.

The group at the National Research Council of Canada was approached by R. U. Lemieux, a professor at the University of Ottawa, to look into the problem of conformations of simple sugars and related saturated six-membered rings by NMR methods.⁶ A productive and beautiful collaboration followed which laid down the fundamentals of conformational analysis by NMR.⁷

Another classical aspect of organic chemistry, namely the phenomenon of tautomerism, was the object of my own experimental work. At that time the equilibrium between keto and enol forms was studied by crude chemical methods such as rapid saturation of the olefinic bond in the enol form by bromine and a back-titration analysis of unused bromine to determine the proportion in the enol form. Spectroscopic methods had been used by Powling and Bernstein.⁸ The earliest NMR study had already been published.⁹ NMR proved to be the ideal way to tackle the equilibrium problem by a physical method. The exchange rate between enol and keto forms of the simplest cases such as 2,4-pentanedione proved to be slow enough on the NMR timescale to resolve separately the spectrum of the keto and enol forms. The position of the equilibrium was easily measured using signal intensities, and the effect of different solvents on the equilibrium was studied by NMR for the first time. It is remarkable that the equilibrium measurements of Shoolery et al.⁹ and Reeves¹⁰ made at 30 MHz and 40 MHz proton frequency, respectively, have stood the test of repeated measurements with much better equipment. My own work was extensive enough to illustrate that the keto–enol conversion rate could be greatly increased in basic solvents such as amines. The NMR method remains the best manner of studying tautomeric systems. This early investigation provided a model case of chemical exchange between three sites in a molecular system; namely, the keto methylene protons, the –OH proton, and the olefinic proton.

The activity of the Canadian group in pioneering the application of NMR to chemistry touched on many fields which were to be the object of my own future research. The study of chemical exchange by NMR is a case in point. The theoretical basis for such studies was already published.¹¹ The line broadening from chemical exchange of protons became evident in many of the spectra taken during the period in Ottawa. The exchange of protons among ethyl alcohol molecules modulates the spin–spin coupling of the –OH group

protons with the methylene protons. This exchange is catalyzed by hydronium ions which lead in very low concentrations to the collapse of the triplet –OH resonance of ethyl alcohol to a single sharp resonance.¹²

Leonard W. Reeves. b 1930. B.Sc., 1951, Ph.D., 1954, D.Sc., 1965, Bristol University, UK. Postdoctoral research associate of Joel H. Hildebrand, University of California, Berkeley, 1954–56; NRC postdoctoral fellow with W. G. Schneider in Ottawa, Canada, 1956–57; Junior Fellow of Mellon Institute Pittsburgh, 1957–58. Assistant, associate, and full professor, University of British Columbia, Vancouver, Canada, 1958–69; Professor, University of Waterloo, Canada, 1969–present. Introduced to NMR by W. G. Schneider in 1956 and used NMR as a research tool since that date. Approx. 165 publications. Research interests: hydrogen bonding, solvent effects, and tautomerism; detailed studies of chemical exchange using lineshape functions and Carr–Purcell–Meiboom–Gill measurements of dependence of T_2 on pulse repetition rate in an exchanging system; use of NMR as a tool for discovery and investigation of aqueous lyotropic nematic and cholesteric liquid crystals.

Richards, Rex: Development of NMR in Oxford

Rex Richards

Oxford University, Oxford, UK

INTRODUCTION

This is a very personal account of some of the stages which I found particularly exciting in the research in my laboratory at Oxford on magnetic resonance. The considerable body of work could not have been done without the collaboration of the many very able young people who worked there with me, and who due to lack of space I cannot mention individually; but I think many of them shared with me some of the more thrilling moments as well as the inevitable frustrations and periods of exhaustion which so often come in research and especially in instrument development.

My interest over the years has been in attempting to demonstrate new ways in which NMR can usefully be applied to scientific problems and this has often involved the construction of our own spectrometers when commercial instruments were either too expensive for us or too inflexible for our purposes. These homemade instruments did not always have the performance we had hoped for; in those cases we used our ingenuity to find problems to which they *could* be applied. My story starts in 1948, soon after I had been appointed as a Fellow and Tutor of Lincoln College; although this was technically a seven-year appointment, I had sufficient confidence to feel that I could embark on something quite new and need not worry about how speculative it was or whether it was likely to yield immediate publications.

EARLY DAYS

When Bernard Rollin came to visit my laboratory some time in 1949 he remarked 'My word! This really is heat, light, sound, electricity, and magnetism!' That was my first NMR apparatus, built from surplus Royal Air Force electronics and a small 4 in. magnet built by Tickfords to a design from the Clarendon Laboratory. There were some massive, already quite elderly, power supplies giving off a good deal of heat, and, with the loose laminations of their transformers, also emitting a loud hum. The valves (tubes) glowed brightly and the 60 V bank of accumulators drove the magnet to produce a field of about 0.3 T in a gap of about 1.5 in.

The purpose of Bernard Rollin's visit was to see how I was getting on, and give helpful advice. He had made NMR measurements several years before; indeed he published his first observations of NMR in 1946¹ very soon after the original announcements from Harvard and from Stanford. Rollin used the simplest possible system in which a signal generator passed an appropriate radiofrequency through a high impedance to a tuned rf sample coil, which was thus supplied from a constant

current source. The voltage on the coil was measured with an rf amplifier and homodyne (phase sensitive) detector; when energy was absorbed in the coil the voltage across it dropped and an NMR signal could be detected. Rollin and Hatton used this simple system to measure proton resonances in liquid and solid hydrogen down to 1 K; they described this work as early as 1949, as well as measurements of deuterium, aluminum, and copper resonances.²

Casting around for something quite new to do, I noticed the announcements of the observation of NMR from Harvard and from Stanford Universities and it occurred to me that this new effect might have applications in chemistry. On making enquiries in the Clarendon (Physics) Laboratory, I found that Bernard Rollin had already been making measurements, the publication of which I am afraid that I had overlooked! He was, however, very discouraging; he thought it was all much too difficult for a chemist and could not see much likelihood of its use in chemistry anyway!

However, Linus Pauling was visiting Oxford at about that time and frequently dined in Lincoln College with his old friend N. V. Sidgwick, who was my predecessor as tutor there. One night I told him about the discovery of NMR and his response was 'Well, Rex, the one thing I've learned is to take no notice of the advice of physicists!' So I went back to Bernard Rollin and told him I had decided to have a go anyway, and from then on he could not have been more helpful. That is why he called in to my laboratory to see the first NMR signal I had observed.

By now the big papers from Harvard³ and from Stanford⁴ had appeared and the possibilities of this new technique seemed to me to be very exciting. My first thought was to measure spin-lattice relaxation times in water in the presence of transition metal ions and various ligands. However the only method of measuring T_1 available to me at the time was the progressive saturation method, and I soon realized that, in my hands, it was simply not accurate enough.

DIPOLAR BROADENING IN SOLIDS

So the next thing to turn to was T_2 by measuring linewidths and shapes. The magnet had very limited homogeneity, so only broad lines could be measured and this meant working with solids. By this time I had seen the advantages of using an rf bridge and adopted a twin-T system described by Tuttle. This very much improved the sensitivity of the whole apparatus, the only commercial components of which were the magnet, a few second-hand power supplies, and a radiofrequency signal generator from surplus radar sets. All the rest of the equipment was built in the laboratory from components obtained by carefully unsoldering them from ex-service racks of electronics of mysterious and unknown (to me) function, which we were able to get at virtually zero cost. My research training with H. W. Thompson in infrared spectroscopy had taught me many laboratory arts and crafts and to be ready to improvise and have the confidence to make whatever is needed; an excellent preparation for the early days of NMR!

I studied the important paper by Van Vleck on second moments and dipolar broadening, and the Ph.D. thesis of Bloembergen, but found them pretty heavy going at the time; and it was only the frequent and patient exposition by Ken Stevens, then working with Maurice Pryce in the Clarendon

Laboratory, that helped me to grasp these vital ideas clearly. A paper by Luzzatti in Paris had recently interpreted the X-ray patterns of nitric acid monohydrate crystals in terms of hydrated HNO_3 molecules, and this presented a good opportunity to try out the NMR method. Working with John Smith, my first NMR graduate student, various acid hydrates were frozen and their NMR spectra measured at 90 K (we used liquid oxygen in those days!). Unequivocal results were obtained showing that some crystals contained the H_3O^+ ion, whereas for others the crystals were not ionic; it was also possible to measure the H–H distances.⁵ I think this may have been the first occasion on which an unknown chemical structural problem was solved by NMR, though of course the H–H distance in calcite had been measured in classical work by Pake and Purcell; it was certainly very exciting to find that NMR could give such a clear-cut result for a chemical structural problem, even though the problem itself was not of earth-shattering importance!

It proved easy to find simple structures where there was ambiguity about the positions of hydrogen atoms, and my young colleagues and I published a series of papers of this kind over a number of years. Initially we plotted the resonances point-by-point at different fields across the resonances, but we soon changed this to automatic recording by coupling a potentiometer to the chart motor of a recorder, used it to drive a power supply for the field scan, and fed the output of the homodyne amplifier to the recorder. We studied a wide variety of problems, including the determination of the structure of the NH_2^- ion, the structures of perborates, perpyrophosphates, and percarbonates, and showed how the liquid/solid content of fats could be determined, a method now used routinely in industry. Linewidths were often measured from 20 K to 400 K thanks to the ready availability of liquid hydrogen, which was dispensed in the Clarendon Laboratory with warnings to treat it with as much respect as you would gasoline! Changes of linewidth with temperature often showed clearly the type of molecular motion causing the line narrowing, and estimates of the potential barriers to the motion could be obtained; some of the measurements made between 1951 and 1956 were later confirmed, but with greater accuracy, by neutron scattering.

CHEMICAL SHIFTS

The discovery of the chemical shift was of immediate significance to anyone brought up in the early days of infrared spectroscopy, and we set to work to build a better magnet with the very limited funds at our disposal. We constructed an electromagnet with 11 in. pole faces and a gap of 2 in.; it had two sets of coils, one of low impedance driven from a stable power supply, and another of high impedance. The many miles of wire were laid down by hand by me over a period of some weeks! The high impedance coils were driven through series tubes and regulated with a simple NMR feedback loop. In spite of much care and adjustment the performance of the magnet was not good enough for proton shifts, so the obvious answer was to use it to study heavy nuclei, and for this purpose we constructed a simple spectrometer using a 'Pound' marginal oscillator with which we were able to study a very wide range of chemical problems. For example,⁶ cobalt chemical shifts were related to the optical spectra of a wide range of complexes and to their respective temperature dependencies; the results

were interpreted in terms of the ligand fields and provided an improved value for the absolute magnetic moment of the ^{59}Co nucleus. Measurements were also made on thallium, gallium, indium, and many other elements.

PERMANENT MAGNETS

By this time, more detailed study of magnet design and consideration of the factors affecting homogeneity suggested that a well-designed permanent magnet might give a very cost-effective solution for real high-resolution NMR. I was fortunately able to raise £2000 to build one and to persuade the Mullard company to do it for this sum. Robert Pound spent some leave in Oxford in the early 1950s, and he kindly recommended me for a Research Fellowship at Harvard. I went off to Cambridge, MA from January to July 1955, spending most of the time in the Physics Department. Working in Pound's laboratory, attempting to see the pure quadrupole resonance in D_2O ice, taught me a great deal about electronics and practical NMR. Attending a course on magnetic resonance by E. M. Purcell and then listening to his patient explanations of the physical principles underlying the theory, gave me an insight into some parts of physics which I doubt if I could ever have gained from a study of the literature. I also got to know Ionel Solomon, visiting from Paris, who was doing some very elegant experiments on HF and demonstrating the nuclear Overhauser effect. Whilst in the USA I met Marcel Golay at the Perkin-Elmer Corporation, an inventor of real genius. In the course of conversation over dinner, I told him about my design for a permanent magnet and about the problem of compensating for residual field inhomogeneities arising from imperfections of gap geometry and from the grain structure of the pole pieces.

Some time after I had returned to Oxford, I had a letter from Golay setting out a detailed theory of a design for a set of correcting coils which could, in principle, cancel out any field gradient with a set of orthogonal adjustments. He made the coils initially by embroidering them on calico, and after getting very encouraging results he had some sets of printed circuits made and very kindly sent me one. We installed this on the Mullard permanent magnet and they worked extremely well, though the adjustments were far from orthogonal and required a good deal of patience and skill. This permanent magnet became the basis of a very simple and reliable high-resolution spectrometer; although the field, at 30 MHz for hydrogen, was very modest, the field value and the very good homogeneity were remarkably stable.⁷ We used this instrument to explore a wide variety of high-resolution NMR applications many of which would seem commonplace today. At 30 MHz many of the spectra were strongly coupled so that detailed analyses of systems such as $\text{A}_2\text{B}_2\text{X}$ or $\text{ABB}'\text{X}$ were needed. We studied solvent effects in some detail and some could be interpreted in terms of weak molecular associations. This simple NMR spectrometer was subsequently used as the basis of a series of relatively inexpensive but reliable instruments manufactured by the Perkin-Elmer Co. Ltd. in the UK, and later by other companies.

Meanwhile, the studies of the chemical shifts of heavy nuclei were proving so interesting that I was able to purchase a Varian wideline spectrometer, which we modified in various ways to allow frequency scanning over small ranges and

to improve very much the precision of chemical shift measurements. This instrument was used to study resonances of nitrogen, phosphorus, the halogens, the alkali metals, platinum, and vanadium, in a wide range of materials.

DYNAMIC NUCLEAR POLARIZATION

In the late 1950s, papers appeared describing a range of studies on the electron nuclear Overhauser effect and ways of producing strong dynamic nuclear polarization. This struck me as worth investigating to see whether there were any chemical applications, to understand the phenomenon more thoroughly, and to see whether this effect could be used in a practical way to enhance the signal-to-noise ratio of the weak nuclear resonances. We mounted a major effort and constructed two spectrometers,⁸ one using X-band microwaves (about 3 cm) and another Q-band (about 8 mm); both used permanent magnets with excellent stability and reasonably good resolving power, and were combined with high-resolution spectrometers at the appropriate rf frequencies.

We learnt a good deal about the mechanisms of nuclear relaxation, observed some quite fascinating effects including cases where scalar coupling occurs between an unpaired electron in a dissolved radical and the nucleus of a dissolved molecule,⁹ and where nuclear polarization surges from one nuclear species to another during the varying relaxation times of the nuclei,¹⁰ and were able to measure the spectra of some very weak resonances in favorable cases.¹¹ But it became clear that the use of dynamic polarization to get an order of magnitude improvement of signal-to-noise would not have any general application. It would be limited to substances which do not react with the free radical required, and to solutions in mobile liquids with low viscosities, though this latter difficulty could, in principle, be overcome by carrying out the polarization at low fields and transferring the polarized sample to a high field in a time short compared with T_1 .

So after publishing some 22 papers on dynamic nuclear polarization, we dismantled the spectrometers and used the components for other work; nevertheless I believe there is still some fascinating work to be done on these effects. An article published in 1967 summarizes my views at the time about the limitations of using dynamic nuclear polarization for NMR work and particularly in biochemistry.¹² Although the chemical applications of these effects were limited, some of these experiments provided beautiful illustrations of the physics of nuclear relaxation, and a subtle method of studying molecular interactions during collisions in liquids.

SUPERCONDUCTING MAGNETS

The commercial production of Nb/Zr superconductors in the early 1960s brought the possibility of the construction of higher field homogeneous and persistent magnets, and indeed Varian Associates were very quick to take advantage of this and produced their pioneering 220 MHz spectrometer. This instrument was too expensive and too inflexible for our purposes at Oxford, so I resolved to raise funds to develop a magnet ourselves, knowing that Martin Wood (now Sir Martin) had already made a small magnet at the Oxford Instrument

Co., and the engineers there were rapidly acquiring the skills required. It was agreed that Oxford Instrument Co. would build two magnets; the first to be a small model to test the design details and the second, a bigger one, to take advantage of lessons learnt from the first. At the same time we thought hard about many details of magnet and spectrometer design and our thoughts at that time were published.¹³ This paper was followed a few years later by further reflections containing some novel ideas on spectrometer design in 1975¹⁴ and again in 1976.¹⁵ These papers give a good idea of the care and thought needed for good instrument design, and illustrate how important it is to decide what are the critical parts of the instrument to which particular attention must be given and what are the less important parts. Of course, one sometimes finds that aspects you thought were going to be very difficult (for example superconducting joints) are solved quickly, and others expected to be easy (such as the cryostat) set you back more than expected!

The construction of the first magnet went reasonably smoothly after tiresome problems with thermal oscillations in the cryostat. The Nb/Zr conductor was not very stable and in the early stages we had some rather dramatic quenches of the magnet, but these problems were soon overcome and the magnet performance vindicated the careful designs of the Oxford Instrument engineers. The room temperature gap was only 2.2 cm, yet it produced a truly persistent field of 5 T and the field homogeneity could readily be adjusted to about 1 ppm over 1 cm³ without spinning. This seemed too good to treat purely as a design exercise, so we designed a spectrometer to use the magnet; although the homogeneity was not good enough for proton high-resolution work, there were plenty of other nuclei to study.

The main problem was the small room-temperature bore, and we solved this by extending an original idea by Redfield and making a crossed-coil probe with an overall diameter of a little less than 2.2 cm which incorporated means for achieving separation of the crossed coils by 100 dB, for applying local homogeneity corrections, for temperature control between -100 °C and +100 °C, and to take spherical or cylindrical samples of 8–9 mm diameter.¹⁶ Chemical shifts could be measured with considerable precision and the instrument was used for a variety of measurements. For example, we studied the resonances for the alkali halides in salt solutions down to quite low concentrations in water and mixed solvents, and interpreted the shifts in terms of ionic collisions using the Debye–Huckel theory; the mechanisms of the shifts were also disentangled.¹⁷ The shifts of cesium resonances between water and D₂O were shown to be due to changes of the water structure rather than to the different weights of the water molecules.¹⁸

In the meantime Oxford Instruments were building the second magnet using the newly available Nb/Ti conductor which was much more stable than Nb/Zr. This magnet was persistent at about 7.5 T (320 MHz for protons) in a 3 cm room-temperature bore and has been in use more or less continuously since 1969. Its homogeneity could be adjusted for proton high-resolution work, though with some considerable difficulty because there were significant gradients of quite high order, and I guessed that this was because the bore was still rather

small so that the sample coil was rather close to the inner windings.

BIOLOGY

By the late 1960s, I had become convinced that technical developments were going to make it really practicable to use NMR to study biological problems. Of course a good deal of work of this kind had already been done, and indeed we had made some proton relaxation enhancement measurements ourselves, but the complexity of biological molecules was a major problem for NMR at the time. So I decided to aim the new magnet particularly at phosphorus resonances, on the grounds that our new spectrometer would be sensitive enough and the phosphorus spectra would be simpler than the proton ones.

In 1969 I was appointed to be Warden of Merton College and Professor R. R. Porter very generously welcomed me and my colleagues into the Biochemistry Department with all our equipment and engineering. This was a big decision for me (and no doubt for him!), but in the event the next 10 years proved to be among the most thrilling in my life, quite apart from the immense pleasure of being the head of an Oxford College and, together with my wife, getting to know a large number of tremendously able young people in many disciplines.

The obvious success of the 7.5 T magnet made it clear that the Oxford Instruments design was a good one and should be exploited immediately. At the same time, it was clear that a larger bore was required to give more room for the probe and to make homogeneity adjustment easier, and since Oxford Instruments did not feel ready to embark on complete spectrometer design it was decided to invite Bruker Physik to collaborate with us. I remember a meeting in my dining room in Merton College at which representatives of Bruker and of the Oxford Instrument Co. agreed with enthusiasm to work together. It was also decided that the same basic design of magnet was to be used, with the bore increased, and the field reduced to a value corresponding to 270 MHz for protons. This was a field just three-times the field used in the standard Bruker 90 MHz spectrometers at that time. The new 270 MHz magnet was a great success; it had excellent resolution and stability, and is still in use in Oxford some 20 years after its construction. It formed the basis of a long line of high-resolution magnets manufactured by Oxford Instruments, the latest of which is a 750 MHz persistent magnet in use in Oxford for proton resonance work on proteins. The first 270 MHz magnet was exploited energetically by I. D. Campbell, C. M. Dobson, and R. J. P. Williams in very early studies of the NMR spectra of lysozyme and other small proteins.¹⁹

At the same time, David Hoult and David Gadian developed a new pulsed phosphorus spectrometer for the 7.5 T magnet which was quite sophisticated for the time and had a good performance. A sample size of 8 mm diameter by 1.5 cm height was used and, with spinning, linewidths of less than 1 Hz at 129 MHz were obtained with spinning sidebands less than 1% of the main signal. At that time we did not have an online computer but only a digital memory system into which the output could be dumped. We tried reading out the data on paper tape and then processing it offline on a main frame computer, but this was very slow and frustrating when the

paper tape reader or punch made errors. David Hoult therefore designed and built an analog Fourier transformer;²⁰ it was a very ingenious idea and worked remarkably well. When small computers became available, however, we naturally took advantage of all the power they provided.

The great advantage of having moved into the Department of Biochemistry was that we were surrounded by people who knew what problems were worth tackling and how to handle the complex materials involved. In particular, we were able to start a long and fruitful collaboration with Dr George Radda and his colleagues who were very quick to see the possibilities of NMR techniques and ready to make the effort to understand them.

The 7.5 T instrument was used initially to do a thorough study of the effects on the chemical shifts of phosphorus resonances of typical biological materials of temperature, pH, ionic strength, and the presence of other salts in the solution. The effects on the relaxation times of traces of paramagnetic ions, dissolved oxygen, chemical exchange, and shift anisotropy were also studied, and by then we felt ready to tackle some real problems. One set of experiments was concerned with the phosphorus resonances of the head groups of model and biological membranes; examples are the linewidths and chemical shift anisotropies in oriented DPL/cholesterol membranes²¹ and studies of unsonicated phosphatidylcholine liposomes.²²

Another problem we studied was concerned with substrate binding to phosphoglucutase,²³ followed by the study of enzyme-bound phosphates in phosphoglucutase, glyceraldehyde-3-phosphate dehydrogenase, and phosphorylase. Because we were members of the Oxford Enzyme Group which was studying the glycolytic pathway in particular, it was also decided to start to look at the phosphorus resonances of muscle extracts. The extracts initially showed only inorganic phosphate, but when a little glucose-1-phosphate was added, the formation of glucose- and fructose-6-phosphate could be seen and their proportions were as expected. Addition of ATP then showed the gradual formation of fructose diphosphate and AMP or IMP.

Many experiments of this kind were done, and it could be shown that glycolysis was fully operational in these extracts with appropriate additions. There was speculation at the time about whether there was any hope of observing these processes in intact muscle, but the expectation was that the relaxation times would be too short. Nevertheless an intact rabbit muscle was placed in the spectrometer and to everyone's surprise five clear resonances were obtained. Initial attempts to repeat the experiment failed, until it was realized how easy it is to allow the glycolysis of an excised muscle to run down before measurements can be made. As a result of this very exciting experiment, attention was transferred to the hind leg of the rat because it was found to be much more easily excised without damage and, of course, had been very extensively studied by classical methods.²⁴

Techniques were developed for maintaining perfused organs in the spectrometer. This presented some formidable experimental problems because of the very limited bore of the magnet, but they were solved by a combination of the skills of the physiologists who found ways of keeping the tissue alive inside the magnet bore and our experience in the design of NMR probes of various kinds. Collaboration with D. Wilkie and his colleagues at University College, London, led to a

careful reanalysis of muscle metabolism in working muscle, which largely confirmed earlier work by freeze-clamp methods but with greater accuracy. G. K. Radda and his colleagues extended the measurements to perfused kidneys, liver, and heart.²⁵ All this work was done on the original 7.5 T magnet and spectrometer in spite of the very limited sample size, and of course it initiated related studies in many laboratories.

As magnet technology developed, larger bores became available and a magnet was installed in Oxford with a 10 cm bore in which whole animals could be studied and even appropriate human limbs. There are, of course, now many instruments being used to study the spectroscopy of phosphorus, and indeed hydrogen, shifts in human patients, and there seems no doubt that this technique will be a very valuable addition to magnetic resonance imaging for medical research and diagnosis.

In 1977 I became Vice-Chancellor of Oxford University and my active participation in day-to-day laboratory work inevitably ceased. Looking back over those years of research, I realize how fortunate I was to have a relatively secure position so early in my career, and wonder whether young people today can afford to take the risks that I felt quite able to take then; I certainly hope that some can. I also realize how important it is not to rely solely on commercial apparatus, but to have the confidence to build equipment oneself when necessary, and not to be put off by the myth, often cultivated by instrument manufacturers, that this is very difficult (though they are often right!).

Rigden, John S.: Rabi's Resonance Method

John S. Rigden

American Institute of Physics, College Park, MD, USA

Editor's Note: The following article is taken from 'Rabi: Scientist and Citizen', the definitive biography of I. I. Rabi, published in 1987. This excerpt is used with the permission of the publisher, Basic Books, New York.

The magnetic resonance method was born in the fall of 1937; however, it was in the making for many years. We shall begin in 1931.

How is the feeble glimmer of a star measured against the lustrous brilliance of the Sun? How is the Sun's brightness kept from swamping the faint light of a star? These questions are analogous to the one that faced Rabi early in 1931. He wanted to measure the magnetic moment of a nucleus in the way that Stern had measured the magnetic moment of a silver atom. The problem was that an atom has a magnetic moment about 2000-times larger than that of a nucleus. The question, How can the minute nuclear moment be measured in the face of the swamping effect of the large atomic moment? was answered by the Breit-Rabi theory in 1931.

In the Stern-Gerlach experiment, a strong magnetic field is used to deflect the moving beam particles. This *strong* field acts directly on both atomic and nuclear magnetic moments, and 99.95% of the resulting deflection is due to the large atomic moment. There is virtually no chance of identifying that 0.05% contributed by the nucleus. However, Breit and Rabi showed that if a *weak* magnetic field is used, the tiny nuclear moment is effectively joined with the large atomic moment so as to affect distinctively the pattern of the deflected beam. For example, a strong magnetic field, acting on the large atomic moment, would split a beam of hydrogen atoms into *two* subbeamlets; on the other hand, a weak magnetic field, acting on the atomic moment coupled with the nuclear moment, would split the beam into *four* subbeamlets. Thus, in a weak deflecting field, the nuclear magnetic moment exhibits itself in a definite way. It was on the basis of this theory that Rabi and Cohen began to design and to build a state-of-the-art molecular-beam system in 1931.

The physics department at Columbia was content with Rabi's return to molecular beams. No one hindered him, but neither was there robust support. Financial backing was meager. Anyone, however, interested in physical results rather than splashy equipment, and willing to work at taking data rather than demanding the latest piece of hardware to ease the burden, could do a lot of physics—especially in those days—on a shoestring. As in his high-school days when he built a radio station out of parts scavenged from the streets, alleys, and back lots of Brooklyn, Rabi and Cohen assembled a simple Stern-Gerlach deflection system. This was the first step in the evolution of the magnetic resonance method.

In the simple deflection method, a beam of atoms or molecules passes between the poles of one magnet. These poles are shaped in such a way as to produce a magnetic field stronger at one pole than at the other. This varying, or inhomogeneous, field exerts a force on the magnetic moment

of a beam particle as it passes between the pole faces. The beam is long and narrow—a fraction of a millimeter in thickness. The magnetic deflecting force acts at right angles to the beam particle's velocity so as to add to its straight-ahead velocity a small sideways velocity. As a result, the beam particles strike the detector at a position that is slightly shifted, either to one side or the other, from the center position of the undeflected beam.

The principal difficulty with the simple deflection method is that the particles in the beam move with a whole range of velocities. The average velocity of the beam particles depends on the temperature of the source from which they emanate. Most particles have velocities that are near the average velocity; like any quantity of a statistical nature, however, other velocities can be smaller or larger than the average value. Since slow particles are deflected more than fast ones, the deflected beam is not a sharp replica of the undeflected beam, but is smeared out. To interpret the smeared-out deflection pattern, one must make theoretical and experimental assumptions and do extensive analysis—tasks that suited neither Rabi's disposition nor his taste.

A second difficulty with the simple deflection method is that the magnetic-field inhomogeneity must be known: that is, the magnetic-field strength must be calibrated point-by-point. Such calibrations are not only irksome but also impossible to do with great precision. Thus, there is an inherent uncertainty in the strength of the deflecting field, resulting in an inherent uncertainty in any deflection that is measured.

And, most important, the simple deflection method did not allow Rabi to have his answer 'by the end of the day'.

Rabi wondered what combination of forces could be exerted on the beam atoms so that they would reveal their secrets more directly. How could the featureless smear of the deflection pattern be transformed into a pattern with features that conveyed the nuclear spin of sodium just by looking? 'My attitude towards physics . . . has always been profound faith and profound skepticism. Profound faith and skepticism. I really felt I wanted to be convinced of nuclear spin. It sounded all right, the theory [of quantum mechanics] explained a whole lot, but I knew enough about the history of physics to know that a good explanation is not necessarily so.'

Rabi relied strongly on his intuition, which allowed him, in a manner of speaking, to put himself into the beam and, along with the other beam particles, experience the sudden jolts and subtle nudges as he streamed through the apparatus. As Polykarp Kusch has said, 'He [Rabi] appears to ride around on the electrons within an atom or asks the question, "If I were an electron, what would I do?" Possibly, through sheer force of character he gets the electron to do precisely that.'¹

So, Rabi rode the sodium atom, first by clinging to an electron, then by sitting on its nucleus. He could feel the beam split decisively into two beamlets by the force of a strong magnetic field acting directly on the large magnetic moment of the sodium atom's outermost electron. If he could now block out one of these beamlets and thus allow only one to continue on its way into a *weak* and *reversed* magnetic field—weak, so that the field would gently separate the beamlet into still smaller beamlets by acting on the combination of atomic and nuclear magnetic moments, and reversed so that the separated beamlets would be sharpened by collapsing the spread resulting from the difference in deflections between the fast and the slow atoms as they passed through the first

field—then he would need another strong (and also reversed) field to bring the whole pattern of separated and sharpened beamlets back toward the center of the apparatus where the individual beamlets could be detected. If the nuclear spin were I , $(2I + 1)$ beamlets should be detected.

Rabi discussed his ideas with Cohen, and the two men started to work on them. Additional deflection fields were added to the system: the first split the beam into two parts; the second subdivided the beam still further, depending on the value of the nuclear spin; the third shifted the spread-out beamlets back toward the center of the apparatus for detection. Between the first and second deflecting fields, a slit was added which allowed only one beamlet to continue through the apparatus.

Rabi's ideas were sound, but their implementation raised new problems. He and Cohen started with a beam containing a relatively few atoms, half of which were thrown away, and the remaining half further subdivided. How does one detect the rarefied presence of each little beamlet? A new detection system would have to be developed. One by one, solutions to other problems were found.

One morning, Victor Cohen, unable to wait for the elevator to take him to the fifth floor of Pupin Hall, bounded up the steps two or three at a time. Earlier that morning, he had found the nuclear spin of sodium, and now he wanted to show the world. He went straight to the laboratory and threw the switches that brought life to his apparatus. As the source oven slowly heated to its operating temperature, Cohen checked the pressure gauges. The pressure readings were low, indicating a good working vacuum. By this time, a few other laboratory workers had wandered in, and soon Rabi made his appearance. The timing was perfect, and Cohen called them all over. A steady flow of sodium atoms left the hot oven; half of them wended their way through the three deflecting fields. Systematically, Bill Cohen slowly moved the detector wire across the beam: the signal first increased and then decreased—a signal peak—one beamlet. Cohen continued the slow movement of the detector wire. The signal increased again and fell again—a second beamlet. A third time, the detector signal increased and fell—evidence of a third beamlet. Still Cohen moved the detector wire, and a fourth time the signal increased and fell—a fourth beamlet. How long would this go on? Cohen steadily moved the detector wire as Rabi watched the signal monitor. Would there be another beamlet? Rabi watched. The monitor registered nothing—nothing—nothing. Cohen stopped. The drama was over, but the excitement was about to begin. There were four signal peaks, four beamlets, which meant that the nuclear spin of sodium is $\frac{3}{2}$.

To this day, the sodium result obtained with Cohen stands as one of Rabi's most satisfying experiments:

The world was young and I was young and the experiment was beautiful. It satisfied everything I wanted to see. There was an artistry in it or whatever it is called . . . it just charmed me. These atoms in spatially quantized states, analyze them in one field, turn your focus back, and there it is. Count them! It was wonderful. There I really, I really believed in the spin, there are the states, count them! Each one, I suppose, seeks God in his own way.

To manipulate a beam of atoms in such a finely controlled fashion as to bring the atoms in one distinct quantum state onto the detector was the first big step toward the resonance method.

The importance of this step was twofold: first, it infused the members of Rabi's team with the confidence that they could control the motion of beam particles in subtle ways; second, this first step, though spectacular, was limited. Counting the peaks gave the size of the nuclear spin, but they wanted to measure other nuclear properties as well, properties such as magnetic moments.

One Saturday afternoon in May 1933, Rabi called into his office Sidney Millman, a graduate student who had just passed the departmental qualifying examination and was therefore about to begin his own dissertation research. Rabi invited Millman to join his molecular-beam group and suggested a thesis topic: the determination of the nuclear spin and the magnetic moment of potassium. Rabi talked to Millman about Cohen's work then in progress and suggested that the 'zero-moment' method that Cohen was going to use for the study of cesium might also be applied to potassium. 'This was all new to me and sounded quite exciting,' Millman recalled later. 'I agreed right there and then to start my research.'² He was shown an area in Cohen's laboratory on the fifth floor of Pupin Hall and there began to build his own molecular-beam system.

By the time Millman started his dissertation research, the Rabi laboratory was a pulsating hive of activity. A second laboratory on the 10th floor of Pupin had been started with its own cast of young physicists—mostly postdoctoral fellows. At any time of the day or night, on any day of the week, the lights in the Rabi labs would be aglow and someone would be there working.

The zero-moment method was another experimental technique motivated by Rabi's need for simplicity, his desire for an immediate answer. It had style. The zero-moment method revealed properties of the atomic nucleus with an immediacy whose impressiveness was challenged only by its clarity. The method is based directly on Breit-Rabi theory which shows that, for specific values of the deflecting magnetic field, the *effective* magnetic moment is zero (the *actual* magnetic moment, a property of the nucleus itself, is not zero). This means that, for specific sizes of the deflecting field, all beam particles, regardless of their velocities, will be undeflected (because their effective moment is zero).

Millman could begin an experiment with the deflecting field turned off entirely and line up the detector to receive the full strength of the undeflected beam. The detector signal would, of course, be strong. Then he would turn on the deflecting field and slowly increase its strength. As beam particles were deflected, the detector signal decreased. Then, as the strength of the deflecting field was slowly increased, the detector signal would rise and fall—a peak—indicating that some particles were passing straight through the magnetic field without being deflected. The process was continued until no more peaks appeared. From the number of peaks and from their relative spacing, the nuclear spin could be determined. For his dissertation, Millman studied the alkali metal lithium.

The zero-moment method provided not only nuclear spins but also nuclear magnetic moments. The rendering of these data, however, was neither experimentally nor theoretically straightforward. To begin with, one particular magnetic field strength that allowed particles to pass through undeflected had to be known. In other words, one calibration was necessary (the field inhomogeneity was *not* needed). Even this one calibration, however, proved unnecessary when a new method was developed to generate magnetic fields.

Jerrold Zacharias, a Rabi postdoctoral fellow, doubted that the field between the iron pole faces of a magnet could ever be accurately calibrated. The outcome of his skepticism was a different method for generating a deflecting magnetic field—namely, by electrical currents, which produce magnetic fields. From the geometry of a current, the magnetic field can be calculated directly, and the error-riddled calibration avoided altogether. The trick was to know the geometry accurately.

With Sam Cooley, Rabi's master machinist, the ideas and sketches were translated into hardware. With the smallest of tolerances, a jig was machined to hold two wires in a parallel configuration. The separation of the two wires was known precisely. When these two wires carried an electrical current of known magnitude, the properties of the deflecting field could be calculated directly. Millman, and other 5th floor students, used the two-wire deflecting field and the zero-moment method to determine both the spins and the magnetic moments of several alkali metal nuclei.

The finances of most universities, including Columbia, were strained during the Depression years of the early 1930s, and Rabi got little financial support from the university for his research. When he really needed a piece of equipment, he would go to Dean Pegram and present a carefully reasoned explanation for what he wanted. About this time, however, Harold Urey received a grant of \$7600 from the Carnegie Foundation in honor of his discovery of deuterium. (Urey, a faculty colleague of Rabi's from the chemistry department, would win the 1934 Nobel Prize in Chemistry.)

Well [Rabi later recalled], Urey did one of the most extraordinary things imaginable. He gave me half of it. I had nothing to do with his discovery. What a greatness in Harold Urey—what a tremendous magnanimity to do something like that!

He had a deep faith in me ... He told somebody, referring to me, "That man is going to win the Nobel Prize." I don't know what he saw in me ... but what a tremendous magnanimity! That money set me free. It made me independent of the physics department.³

While Rabi could 'see' specific results or 'feel' the outcome of an experiment, to explain in detail to Dean Pegram was very difficult: 'Besides, Pegram was a wonderful guy, extremely intelligent, and he'd have ideas, too. Next thing I knew we were collaborating, and I wasn't interested in collaboration. All I wanted out of him was money, admiration, and encouragement. With Urey's money I was free. I was able to do things on my own.'

And Rabi needed to be free. His laboratory was growing in people, flourishing in ideas, and expanding in experimental methods. A new method, however, did not necessarily render obsolete an older method. A case in point is the refocusing method developed during 1935. The zero-moment method had one major drawback: it could not be applied to atoms whose nuclei had a spin of $\frac{1}{2}$. The refocusing method could be applied to all atoms. There were advantages with both methods, and both methods continued to be used concurrently. As a consequence, it was not possible to cannibalize old equipment and use the parts in the new apparatus. For the refocusing method, new hardware was required, and new hardware required money. With Urey's money Rabi was free to expand his experimental base and to do so on his own.

Whether with sledgehammer techniques or with graceful, teasing subtlety, the experimentalist cannot get something from Nature without a price. The refocusing method allowed the

vexing problem of the beam-particle velocity distribution to be artfully sidestepped. The outcome of this method, as with the zero-moment method, did not depend on the speeds of the beam particles. The cost of this independence was that the researcher did need to know the magnetic field inhomogeneity.

In the refocusing method, two deflecting magnets were used. Atoms were deflected once, then once again in the opposite direction, so that in the end they arrived where they would have arrived had there been no deflection at all. Slow beam atoms were deflected more than fast ones by each magnet; but in the end, all were refocused into the detector.

The experimental procedure was beautifully simple. Beam particles went through two deflecting fields in sequence—the first called the A-field which pushed them one way, then the B-field which pulled them the opposite way. With both deflecting fields turned off, the detector's location was adjusted so as to register a strong signal and thereby indicate that it was receiving the undeflected beam. Then the B-field was activated. The B-field split the beam into two major subbeams. One subbeam missed the detector to the right, while the other missed it to the left. The detector signal was essentially zero.

Next, the A-field was activated. Slowly the deflecting field was increased in strength from zero to ever larger values. Atoms in the quantum state identified with the largest effective magnetic moment were the first to be refocused into the detector. The detector signal rose, then fell. Quantum state by quantum state, beamlets of atoms were slowly swept over the detector as the attendant rise and fall of the detector level signaled their passing. From the number of peaks detected and from a knowledge of the magnetic field characteristics, both the nuclear spin and the magnetic moment of an atom could be determined.

Nuclei have intrinsic spins (angular momentum) and magnetic moments. The magnetic moment has both a magnitude and a sign. In 1935, the sign was missing. The sign of a magnetic moment can be either plus or minus: if the spin and the magnetic moment have the same space-quantized direction, the sign of the moment is plus; if these directions are opposed, the sign is minus. The signs of nuclear magnetic moments became important in the mid-1930s as a result of the work on the hydrogens being carried out in the 10th floor laboratory by Rabi, Zacharias, and Jerome (Jerry) M. B. Kellogg, another postdoctoral fellow.

The effect of the signs on their data was subtle—so subtle, in fact, that there was no effect at all. As beamlets of a particular atom were refocused into the detector, the same pattern was observed regardless of whether the sign of the atom's moment was plus or minus. The problem of determining the signs was something like trying to determine whether someone's right hand or left hand is pushing the front-door buzzer.

In 1936, Rabi wrote a theoretical paper (one of the few he ever wrote by himself) in which he analyzed experiments that had been done in Stern's Hamburg laboratory in 1932 and 1933.⁴ The purpose of Stern's experiment had been to answer a question that went back to the days of the old quantum theory, the days when the idea of space quantization strained credulity. The question was, can an atom that is 'clinging' to a magnetic field with some particular space-quantized orientation be shaken loose? Can an atom be made to change its orientation?

Putting the question to the potassium atom, Stern and his associates had sent atoms streaming through a magnetic field in which they would take on a specific spatial orientation. Then Stern played a trick: he arranged for the atoms to leave the magnetic field they were in, and suddenly enter another field—a field whose direction changed from the one the atoms were used to, to a new direction. The question could be asked, would the atoms, upon entering the field with the new spatial direction, stubbornly maintain their original orientation, or would they follow the direction of the changing field?

The Stern group determined that, when the direction of the magnetic field is changed quickly enough, the atoms on passing from one field to another will reorient. It was in this reorientation process that Rabi saw the possibility of determining the signs of nuclear magnetic moments. He described this idea in his 1936 paper. The idea was Rabi's; the work to implement it fell to his students.

In their 10th floor laboratory, Kellogg and Zacharias dismantled the molecular-beam apparatus, stretched it out a bit so that a new magnetic field—the 'T-field'—could be inserted between the two deflecting fields. The T-field was a strange one, its configuration giving it a treelike appearance. The direction of the field went up the trunk and then fanned out to right and left like tree limbs. A beam particle entered the T-field moving *against* the field (from the tips of the limbs in toward the trunk of the tree); and, on departure, the particle moved *with* the field (from the trunk out toward the ends of the limbs). As a particle moved rapidly through the T-field, it 'saw' a magnetic field change quickly from one direction to another; it 'saw' a field that appeared to rotate.

Rabi recognized that if this apparent rotation was synchronized with the precession rate of the magnetic moment (the Larmor frequency), the T-field would exert a tipping force on the magnetic moment and make it flop from one orientation to another. These reorientations would open the way for determining the signs of nuclear magnetic moments.

Kellogg and Zacharias made another addition to the apparatus. They added a barrier between the first deflecting field and the T-field. With this barrier, one of the subbeams coming out of the first deflecting field was stopped before it entered the T-field. By observing the changes in the signal level of the detector as *preselected* beamlets were allowed to pass through the T-field, one could infer the signs of the magnetic moments. It all worked: the T-field did its job.

What Kellogg and Zacharias did on the 10th floor, Henry Torrey, another Rabi graduate student, did on the 5th: he built a refocusing system complete with T-field. There he, along with Millman and Zacharias, determined the signs of the nuclear magnetic moments for the alkali metals.

The T-field was the last significant modification made to Rabi's apparatus before the advent of the magnetic resonance method. The refocusing method together with the T-field provided a provocative experimental milieu. With deflecting magnets laid out along the flight paths of the beam atoms, Rabi and his crew learned how to exert a fine sense of control over beams of particles. They learned where and how barriers and gates could be set up to allow only select beamlets to pass on to the second deflection stage and, from there, to the detector. They learned detection techniques and the idiosyncrasies of various deflection systems. They learned how to make atoms flip from one space-quantized orientation to another and to detect a reorientation. The fingers playing over the controls of

the apparatus had a feel for beams. Everything was poised for the next step.

Concern with experimental accuracy and precision occupied the thoughts of Rabi and his students during the 1930s. They had started with the simple Stern–Gerlach experiment with uncertainties of at least 10%. The zero-moment method was the best of all and, when it worked, it worked well. The refocusing method produced results with uncertainties of about 5%. The best of their experimental results prior to the resonance method carried uncertainties of about 3%.

The uncertainties associated with these results were not altogether due to the design of either the apparatus or the experiments. Limits were also established by physical theory. Neither the zero-moment method nor the refocusing method yielded the value of the magnetic moment directly; rather, the quantity directly measured is the energy difference between two quantum states. To get from this number to the value for the magnetic moment, one had to use theory—theory that was only approximate. The magnetic resonance method inaugurated a new era of precision: the experimental and theoretical difficulties that limited the precision of earlier results no longer existed.

The idea in Rabi's 1936 paper, the one that led to the determination of the signs of magnetic moments, came to him as he walked up the hill from his home on Riverside Drive toward the campus:

One day I was walking up the hill on Claremont Avenue and I was thinking about it [the sign of the nuclear magnetic moment] kinesthetically with my body. Now, yes, I was thinking about this as follows: here's the moment and it's wobbling around in the direction of the field and [to find] the sign was to find out in which sense it was wobbling. To do this, I have to add another field which goes with it or against it. This is the idea, just concretely. The whole resonance method goes back to this.

His intuition was sound, and atoms did reorient in such a way that the signs of their magnetic moment could be determined. But Rabi's 1936 paper was essentially qualitative, and later that year he set out to extend his earlier ideas and to develop them into a quantitative theory of atomic reorientations. His theory was published in 1937.

This paper, entitled 'Space Quantization in a Gyration Magnetic Field,' presented a theory that became the basis for the magnetic resonance method.⁵ After World War II, this was the paper cited independently by both the Harvard physicist Edward Purcell and the Stanford physicist Felix Bloch in their papers announcing the discovery of nuclear magnetic resonance (NMR) in bulk matter. Today, more than 50 years later, this paper is cited by laser physicists who use Rabi's 'flopping formula', derived in the 1937 paper, thus showing how a great paper can be applicable far beyond the immediate intentions of its author.

In this paper, Rabi derived an expression that gives the probability that an atom will be reoriented by a magnetic field that changes direction (gyrates). By using the T-field, Kellogg, Millman, Zacharias, and other physicists had been observing these reorientations. Rabi wanted both to know more exactly the conditions conducive for reorientations and also to extend the range of applicability of the general method.

As an atom moves through the T-field, it experiences a changing magnetic field. More specifically, the atom 'sees' a magnetic field—first in one direction, then in another. From the atom's point of view, the magnetic field appears

to rotate. Rabi's 1937 paper showed that the critical factor is the frequency of this apparent rotation.

The frequency of the apparent rotation is significant because of a second frequency. When an atom with a magnetic moment is placed in a magnetic field, its motion is like that of a spinning toy top. The axis of a spinning top precesses (rotates) around the vertical direction. As the spinning top slows, the precessional circles get bigger and bigger until the top topples to the floor. Here the analogy breaks down because the spin of atoms is intrinsic and 'never slows down'. But the spin axis of an atom does precess around the direction defined by the magnetic field. Furthermore, this precession occurs with a specific frequency—the 'Larmor frequency'—that depends on the magnetic moment of the particular atom and on the strength of the magnetic field. Hence, Rabi's result. As an atom goes through the T-field, it 'sees' a rotating field—a field rotating with a specific frequency. If that frequency is equal to the atom's Larmor frequency, then the probability for reorientation is relatively large. On the other hand, if that frequency is either much below or much above the atom's Larmor frequency, the probability for reorientation is small.

Rabi's 1937 paper, completed in February and published in April, is the theoretical basis for the magnetic resonance method. The steps needed to implement the method were simple: the T-field had to be replaced with an oscillating magnetic field embedded in a uniform magnetic field. Zacharias remembers sitting in Rabi's office discussing the fact that 'if you apply a radiofrequency [that is, a magnetic field oscillating with a radio frequency], you can make it flop.'⁶ After the basic ideas for this method were in place, however, implementation of the resonance method did not begin for over seven months.

Several factors contributed to the delay. First, there was, in a sense, a backlog of work to finish: namely, determining the signs of the magnetic moments that had been determined earlier; for this task the T-field method was adequate. Second, the T-field method appealed to Rabi: 'It had things in it—splitting the beam, counting peaks, getting the signs of moments.' Third, there was no pressing reason to rush: 'There was this very happy condition that nobody was competing with us. It was such a wonderful period.'

Rabi's happy condition was challenged in September—a challenge answered by the implementation of the resonance method. The Columbia Physics Department and Rabi's laboratory were a natural stopping-off place for European physicists visiting the United States. In September 1937, C. J. Gorter from the University of Groningen in Holland was such a visitor. The previous year, he had unsuccessfully attempted to observe a magnetic resonance effect in a solid sample of lithium fluoride. When visiting Columbia, Gorter, according to Rabi, said, 'Why aren't you doing it this way?' meaning, 'Why aren't you using an oscillating field?' Rabi acknowledges that, 'Gorter's visit was a stimulus. I knew about his work; in fact, he didn't tell us anything we didn't know. But he asked me, "Why aren't you doing it this way?" Well, I liked what we were doing, but I saw that he might go after it and we might get some competition. So I said, "Let's do it." Gorter's visit stimulated me into saying, "It's time to do it the other way."'

Gorter visited on a Saturday. On Monday morning, two days later, the pulsating vacuum pumps connected to Millman's apparatus were shut down, and modifications were started.

The ranks of Rabi's corps of postdoctoral fellows was expanded in September of 1937 by the arrival of Polykarp Kusch and, on that Monday morning, he joined Millman (who by that time had received his Ph.D. degree) and Zacharias in an all-out effort to modify Millman's apparatus so that it could be used for the resonance method. They started with a basic refocusing molecular-beam system. Between the two deflecting magnets that provided the A- and B-deflecting fields, a third magnet was placed. The pole faces of this magnet were flat so that a uniform field, the C-field, was established between them. Embedded in the C-field was a wire loop shaped like a bent hairpin. The loop was connected to a radiofrequency oscillator that sent a radiofrequency current through it. As particles of the beam passed between the sides of the hairpin loop, they were subjected to an oscillating magnetic field—a field that could change the orientation of precessing atoms.

The modifications did not take a long time. With Rabi, Kusch, Zacharias, Kellogg, and other physicists looking on, Sidney Millman made a final adjustment to the collimating slits so that the detector registered the presence of an intense beam. Molecules of lithium chloride were streaming unmolested through the apparatus. Millman turned on the B-field which deflected the beam molecules out of the detector. The detector signal vanished. Millman turned on the A-field and slowly increased its deflecting strength. Everyone watched the detector, waiting for its signal to rise as molecules were refocused back into the mouth of the detector. Molecules left the first deflecting field with a particular spatial orientation. They left the second deflecting field with the *same* spatial orientation and were refocused into the detector. When the detector signal reached full-beam level, everything was ready.

This was the moment. There was no sound except for the pounding vacuum pumps. Millman set the frequency of the oscillator at 3.518×10^6 c/s. His hand moved to the rheostat controlling the current in the electromagnet—the magnet that produced the C-field. Millman steadily turned the rheostat and watched the ammeter that registered the current in the windings of the electromagnet. The current read 110 A. The beam detector was recording a full-beam intensity.

Millman continued to increase the current—111 A—112 A. Rabi's eyes darted back and forth between the ammeter and the beam detector. The full beam was still arriving at the detector: 113 A—full beam. No one spoke. They no longer heard the rhythmic throb of the pumps: 114 A—the level dropped a lot; 116 A—the bottom fell out of the signal level. Much of the beam was no longer being refocused into the detector. There were glints of anticipated excitement in all the eyes fixed on the detector. Millman, with steady hand, continued turning the rheostat: 117 A—the beam was returning to the detector, and the signal level jumped up dramatically; 118 A—jumped up some more; 119 A—back to full-beam strength; 120 A—no change. The watchers stirred restlessly, breaking the tension; 121 A—still no change. The tension broke entirely as cheers filled the lab and reverberated down the corridor.

'Rabi was beside himself,' Kusch said later.⁷ Backs were thumped and hands were shaken. For the first time ever, a nuclear magnetic resonance absorption had been recorded. The nucleus was lithium.

What happened as Millman increased the strength of the C-field? Recall that molecules left the first deflecting field with a particular space-quantized orientation. As they moved through the oscillating field, nothing happened until the current reached

115 A. This current produced a C-field in which the Larmor precession frequency of the lithium atoms almost matched the frequency of the oscillating field (3.518×10^6 c/s); thus, some of the lithium atoms flopped to a new orientation and were not refocused into the detector by the second deflecting magnet. At a current of 116 A, the match was almost exact, and many, many lithium atoms flopped from one orientation to another and missed the detector. It was at this point that the bottom fell out of the signal level. At 119 and 120 A, the Larmor frequency was no longer in resonance with the frequency of the oscillating field, and the probability was slight for a reorientation; hence, they were all refocused into the detector, and the signal was once again large.

Helen and Rabi threw a party that night, and graduate students and postdoctoral fellows came to celebrate. Everyone was exuberant, especially Rabi who circulated in high excitement among the members of his team. Rising above the noise of many simultaneous conversations, a frequent sound could be heard: Rabi's high-pitched laugh.

Although even at that time, January 1938, it was likely that the events of the day might be crowned with a Nobel Prize, no one could have foreseen how important the magnetic resonance method would prove to be—for not only physics but also chemistry, biology, medicine, and the whole of science.

Biographical Sketch

John S. Rigden. b 1934. B.S., 1956, Eastern Nazarene College, Ph.D., 1960, Johns Hopkins University, USA. Postdoctoral research, Harvard University where he published an NMR paper with John D. Baldeschwieler. Faculty member in physics at Eastern Nazarene College, Middlebury College, and the University of Missouri–St. Louis; Director of Physics Programs, American Institute of Physics, 1987–present. Approximately 170 publications. Research specialties: molecular physics, history of physics, physics education.

Roberts, John D.: A Personal NMR Odyssey

John D. Roberts

California Institute of Technology, Pasadena, CA, USA

I was quite improbable material to become an NMR researcher. At the time NMR was liberated from the physicists, I was an organic chemist with substantial experience in synthesis, although I also had great enthusiasm for problems in reaction mechanisms and organic structures. In college, I'd taken courses in mathematics only as far as simple differential equations, I was weak in physics, especially in quantum mechanics and the gamut of electromagnetic phenomena. It could be convincingly argued that I should never be allowed at the controls of the very user-unfriendly early Varian NMR spectrometers. Indeed, in early 1954, when I suggested to Linus Pauling, then Chairman of the Division of Chemistry and Chemical Engineering at the California Institute of Technology, that we absolutely had to have an NMR spectrometer for use by our faculty, he figuratively patted me on the head and opined that it would be much more appropriate to hire a new professorial colleague with expertise in the field so that the required, and expensive, instrumentation (at that time about \$26 000) could be used to best advantages. Possibly true, but in the preceding five years, other perhaps comparably complex instruments, such as the Baird and Perkin-Elmer double-beam infrared spectrometers, were being used with great effectiveness by organic chemists and were rapidly becoming indispensable for modern organic research, even for those doing purely synthetic chemistry. I was sure that NMR would soon prove to be very much more useful than infrared and I wanted Caltech to be in the forefront.

Interestingly, Caltech had been very much in the forefront of NMR earlier through the efforts of Professor Don M. Yost, an inorganic chemist of great perspicacity who perceived that NMR could be used to investigate whether the proton in $[\text{F} \cdots \text{H} \cdots \text{F}]^-$ was centered between the fluoride ions or closer to one than the other. Yost built an NMR spectrometer of war-surplus electronic equipment and studied the problem, in the process training and inspiring one of the great NMR researchers of all time, John S. Waugh. About the same time, another Caltech student, James N. Shoolery got his Ph.D. and went to work for Varian, where he made enormous contributions to the practical use of NMR by chemists in both academia and industry. Unfortunately, Don Yost was of a temperament to change research fields often and with great ease. So, shortly after his NMR period, he switched to research on algebra and the very early opportunity that he afforded Caltech to continue in the forefront of NMR was dissipated.

I had heard of NMR when I was on the faculty of the Massachusetts Institute of Technology and, indeed, was exhorted there by Richard Ogg, a professor of chemistry at Stanford, a birthplace of NMR by Felix Bloch and his co-workers, to pay attention to NMR's promise for chemistry. However, I had too little knowledge of magnetism or radiofrequency phenomena to understand what he said about the applications to chemistry. However, Ogg's enthusiasm certainly impressed me.

The catalyst that convinced me that NMR was important enough to become personally involved was William D. Phillips of Du Pont's Central Research Laboratory, who made many important discoveries that are basic to today's NMR. On a consulting visit in 1954 to Du Pont, Phillips, whom I had known previously as a graduate student at MIT, generously educated me about shifts and couplings and showed me how ^1H and ^{19}F spectra could be used to establish structures. That was wonderful, but I knew that I had to do NMR myself when he showed me how *N,N*-dimethylformamide gave two methyl-group proton signals at room temperature and these coalesced above 120 °C as the result of increased rates of rotation about the C–N amide bond. The prospect of measuring very rapid reaction rates by NMR provided the inspiration for getting an affirmative response from Linus Pauling that 'with NMR, we could investigate the borderline between resonance and tautomerism'. For example, investigating the NMR spectrum of cycloheptatriene with temperature to see if it existed as a rapidly equilibrating mixture of cycloheptatriene and norcaradiene, or was what later would be called a 'monohomobenzene'. The argument was persuasive and we soon ordered a 30-MHz Varian proton and fluorine spectrometer.

The spectrometer arrived in the summer of 1955 already upgraded to 40 MHz, with none other than James N. Shoolery as our Varian installation manager. I had never actually seen an NMR spectrometer before and was blissfully ignorant of how they operated. George Pake's superb articles in the *American Journal of Physics* were my bible for several months.¹ Then, fortunately, Edward Purcell gave some exceptionally clear lectures about NMR in the Caltech Physics Colloquium that were very helpful, as was Felix Bloch's original paper on nuclear induction.² Learning to operate the spectrometer was something else again. A slender 'instruction manual' came with the spectrometer, but it was almost useless for actual operations. Your only hope was to learn by watching the installer.

Our Varian spectrometer was impressive for organic chemists, who thought a large instrument was an infrared spectrometer; a massive 6000-lb electromagnet with 12-in. pole faces driven by a very large power supply topped by an enclosure containing an array of eight white-hot 304TL voltage regulator tubes, each about 10-in. high and cooled by a noisy air blast. Operations were controlled by a console studded with dials, meters, and glowing pilot lights.

Jim Shoolery had become one of the early experts on using NMR to determine organic structures and, when he suggested that we supply an illustrative sample, I tried him out with one of our then current synthetic triumphs, 1,3-dimethylenecyclobutane. Jim used the CRT display, which had a long-persistence, bright-yellow trace, to determine the relative number and kind of proton resonances of the sample. He decreed that, along with other resonances, the compound had a methyl group and a single hydrogen on a double bond. This was bad news until we realized that there could have been a rearrangement in the reaction used to introduce the second double bond and the product was 1-methyl-3-methylenecyclobutene. This demonstration of the power of NMR caused me to abandon almost everything else and essentially to live at the spectrometer to determine its capabilities with the kinds of compounds that we were working on at the time.

The spectrometers of this era were quite unsophisticated by present standards. Resolution on the order of 1–2 Hz could usually be achieved, but changes in line voltage, air temperature or cooling-water temperature, movement of magnetic materials in the vicinity, and so on, caused the spectra to be poorly reproducible, even over seconds. So, when we recorded spectra, we used a relatively high-speed Sanborn recorder that wrote with a hot wire on a narrow strip chart. The usual procedure was to run off 10–20 7-s sweeps and then see if two or more spectra could be found that were essentially the same. Of course, these spectra were heavily contaminated with relaxation wiggles whose shape could be useful, as with 2-methylpropene, to determine accurately small couplings that could not be easily measured directly with fast sweeps.

Our first NMR research project was planned to determine the structure of Feist's acid, and we were able to show that it was a methylenecyclopropanecarboxylic acid.³ About the same time, Jim Shoolery's finding that the NH resonance of pyrrole was broadened at 40 MHz to almost unrecognizability by either ¹⁴N quadrupole relaxation or proton exchange attracted my interest. I showed that the broadening was not caused by proton exchange, because when I raised the sample temperature, the triplet expected from the ¹⁴N–H splitting appeared. Similar results were obtained with amides and amine salts.⁴

I gave my first lecture on NMR in December of 1955 at the University of Rochester, and although I had been using the instrument for some months, I was still not sure how it worked, but fortunately the night before the lecture an important principle suddenly became clear and my seminar went well.

I had told Pauling that I wanted to look at the spectra of cycloheptatriene as a function of temperature, but there were problems in working at other than room temperature. Varian's early contribution to temperature control was a small Dewar flask with a receiver coil wound around the outside. You had to heat or cool the sample to the desired temperature, put it in the probe, and quickly take a nonspinning spectrum. At best, the temperature was uncertain by several degrees. This situation was so unsatisfactory that I designed a probe insert with which it was possible to maintain a desired temperature and allow sample spinning. The details were worked out with Jim Shoolery and patented by Varian.⁵

My first graduate student to become heavily involved in NMR was A. T. Bottini, who confirmed the structure of *N*-ethyl-2-methyleneaziridine by its proton NMR.⁶ We expected the two protons attached to C-3 to be nonequivalent, because the *N*-ethyl group would be on one or the other side of the imine ring and that inversion would be relatively slow, at least on the NMR timescale. However, these protons were equivalent and we decided to see if rapid nitrogen inversion was the cause by lowering the temperature. Despite our primitive temperature controls, we were able to observe a dramatic change in the spectrum at –80 °C.

In connection with our work on cycloadducts from fluorochloroethenes with phenylethyne, we discovered sizable four-bond, cross-ring H,F spin–spin splittings.⁷ From this, we embarked on an attempt to understand more-than-three bond couplings and E. I. Snyder set a record in our laboratory of a nine-bond proton–proton coupling in octa-2,4,6-triene-1-ol.⁸ We also worked on through-space couplings, a subject still of substantial interest.

Our research on rotation about single bonds and shift nonequivalences associated with internal molecular asymmetry was undertaken because Drysdale and Phillips had published spectra that I interpreted to mean that appropriately substituted fluorohaloethanes might possibly exist as stable optical enantiomers at room temperature. Although the chances seemed remote, P. M. Nair investigated the ¹⁹F spectra of 1,2-dibromo-1,1-difluoro-2,2-dichloroethane that is expected to have three staggered rotational conformations.⁹ Two of these conformations are enantiomers that would have nonequivalent fluorines, while the third has a plane of symmetry and would be achiral with equivalent fluorines. The ¹⁹F spectra at room temperature showed only a single sharp resonance line and this meant that either rotation about the C–C bond was fast or else that the achiral form dominated. However, below –30 °C, the ¹⁹F resonances broadened and, at –80 °C, the spectra showed five ¹⁹F peaks as expected for the chiral (with nonequivalent fluorines) and achiral conformations. The ratio of these forms was about 1.4:1. These spectra seem to represent the first case of the use of NMR to show slow rotation about single C–C bonds. Subsequently, we investigated a variety of compounds showing slow rotation at low temperature. An especially spectacular example was provided by Frank Weigert with 1,1,1,4,4,4-hexafluorotetrachlorobutane.¹⁰ A quite unusual case was of rotation of the phenyls of 1,8-diphenyl-substituted naphthalenes discovered by House. We were able to show that these rotations occurred readily because of large steric interactions in the ground state.¹¹

For a brief moment, I thought that nonequivalence of geminal groups might be used as a test for molecular chirality. This notion did not persist and I went through the organic stockroom shelves to find an achiral compound that would also have nonequivalent geminal groupings. Here, I turned up 1,3-dinitro-2-propanol and, indeed, this achiral compound did have nonequivalent –CH₂–protons.⁹ Kurt Mislow, with a flair and love of nomenclature, aptly christened such geminal groups as 'diastereotopic'.

Later, we measured the rate and activation parameters of nitrogen inversion of benzylmethylhydroxylamine by observing the benzyl –CH₂–protons as a function of temperature.¹² An analogous study, one among many applications of this technique to conformational equilibration, led to measuring how fast the double bond of *trans*-cyclodecene turns over against the restraints provided by the methylene groups on the opposite side of the ring.¹³ The free energy of activation was found to be about 11 kcal mol^{–1}, very much smaller than the 35.6 kcal mol^{–1} barrier determined by Cope for *trans*-cyclooctene, a value that allows for isolation of the enantiomers at room temperature. This work was brilliantly carried forward by G. Binsch, later to have a distinguished career at the University of Munich. We also used the diastereotopic protons of diethyl sulfite to show that the ²*J*(H,H) geminal couplings had the opposite sign of the ³*J*(H,H) vicinal couplings.¹⁴ Further, we investigated how far magnetic nonequivalence could be transmitted down a chain to a diastereotopic group from the site of the dissymmetric structural element before the chemical shift difference can no longer be detected.¹⁵

The lack of stability of our first NMR spectrometer was both exasperating and time-consuming. The first real sea change in NMR for organic chemists came with the introduction of the Varian superstabilizer in 1956. Now, the 7-s spectra could be abandoned for 1–2-min spectra and these had much reduced

lengths of the relaxation wiggles and so allowed much better resolution. Our order was put in so promptly that we were shipped Serial #1.

The next sea change in NMR for organic chemists came with the development of the Varian A-60 spectrometer in 1961 which finally put NMR on a par for user friendliness with infrared spectroscopy. It was still a vacuum-tube machine and had fits of temperament requiring tender loving care, but it could be used without a seasoned practitioner hovering in the background. The extension to ^{19}F NMR as the A-56/60 instrument with a temperature-controlled probe was a boon to our research using fluorine NMR for conformational analysis.

When I was invited to speak at a Reaction Mechanisms Conference at Bryn Mawr College in September 1958, it seemed like the right occasion to give a lecture about NMR and its applications to organic chemistry. For this talk I made color drawings and photographed them in Kodachrome. The resulting slides made quite a hit and, even 35 years later, people told me how influential the lecture was for them. The success of this lecture and its many repetitions at universities around the country made it easy to write a short book about NMR basics for organic chemists.¹⁶ Although low-brow compared to Abragam or Pople, Schneider, and Bernstein, the book broke new ground as the first advanced book in chemistry to have four-color illustrations (thanks to the McGraw-Hill's editor, W. A. Benjamin) and the first to use the now widely prevalent spectral problems, where one expects a structure to be derived on the basis of an empirical formula and a spectrum alone.

My second NMR book came about because I was perplexed to understand the quantum mechanics responsible for AA'XX' spin-spin coupling patterns, especially H. M. McConnell's spectrum of 1,1-difluoroethene. Perhaps it was clear in Pople, Schneider, and Bernstein's excellent book, but it was also sure that the book was not written for the likes of me. Desperate, I corralled my then professional colleague, McConnell, sat him down on a 4th of July afternoon and insisted that he explain. It was a rewarding three hours.

It was a propitious time to write a book, before I knew too much and, in particular, before I lost my missionary spirit. It is unlikely that the major textbook publishers would have been interested in getting out a book on such a level of expertise by someone so new to the game, but it was a propitious time for another reason because W. A. Benjamin had just started his own publishing company and wanted to hit the market with something fast and was willing to go to press without such niceties as peer review.¹⁷ 'An Introduction to Spin-Spin Splitting in High-Resolution Nuclear Magnetic Resonance Spectra', the short book with the long title, is now long out of print, but perhaps it could stand another edition. The portrait (mine) on the back of the dust jacket would also have to be a new edition. Unfortunately, the book was written without the benefit of A. A. Bothner-By's LAOCOON program, which enables one to calculate what spectra would look like for a given set of chemical shifts and coupling constants.¹⁸ Even more, LAOCOON could determine a set of parameters that corresponds to a given spectrum by an iterative process. The program and input data were supplied to the computer on punched cards and it was easy to punch as many new cards as needed to change the data set. The program was rather large then, some 500 lines of source code. In recent years, when I rewrote the FORTRAN code in True BASIC

with provisions for revision of the data set in memory and a curve-plotting routine, the program swelled to some 3600 lines of code.

With some knowledge of the analysis of fairly complex splitting patterns, I hoped that we could use proton NMR to solve my UCLA Ph.D. thesis problem carried out with W. G. Young and concerned with the structure of the butenyl Grignard reagent. In a test of proton NMR to study Grignard reagents, J. E. Nordlander found, to our surprise, that 2-propenylmagnesium halides displayed the spectrum of a simple AX₄ system.¹⁹ Furthermore, the spectrum did not change to as low a temperature as we could take proton spectra at that time.

The finding of an AX₄ NMR spectrum for 2-propenylmagnesium bromide was very surprising and could only be understood if there is sufficiently rapid rotation about the C-C bonds to average the expected shift differences for either the classical CH₂=CH-CH₂-MgBr structure or a 2-propenyl anion-Mg⁺Br ion pair. For each of these, one would expect enough double-bond character to one or both of the C-C bonds to create a shift difference for the respective *cis* and *trans* protons; if not at room temperature, certainly at -80 °C. The simple explanation for the results is that the classical structure is, in fact, correct, but that it undergoes allylic equilibration with the MgBr group moving rapidly from end to end. Such equilibration would make the C-C bonds alternate between single and double bonds, and thus permit facile rotation about both C-C bonds so as to make all of the CH₂ hydrogens magnetically equivalent on the NMR timescale. The rapidity of the allylic equilibration was quite unanticipated and we found that it was still rapid even at -120 °C with di-2-propenylmagnesium, prepared to be free of magnesium halides that might be expected to catalyze equilibration.

In 1944, I had concluded from the study of many reactions of the butenyl Grignard reagent that it almost surely had the primary CH₃CH=CH-CH₂-MgX structure. The proton chemical shifts in the NMR spectrum found by E. Nordlander for this Grignard reagent qualitatively confirmed the CH₃CH=CH-CH₂-MgX structure, but there were clear indications of rapid allylic equilibration, even if the primary isomer predominated to an extent certainly greater than 95%.²⁰

These conclusions were confirmed by George M. Whitesides for the 3-methyl-2-butenyl Grignard, (CH₃)₂C=CH-CH₂-MgX, that for stereoelectronic reasons is expected to favor the primary isomer much more than the butenyl Grignard reagent itself. At room temperature, the methyl groups of this Grignard are equivalent, but below 0 °C they have different chemical shifts and, so in this system, at least, it is possible to slow the rate of equilibration between the allylic isomers.²⁰

The problem of determining reaction rates from NMR lineshapes became a priority for our research on the rates of conformational equilibration. Now, a new theoretical barrier arose, that presented by density matrix formalism. Having not really recovered from grappling with spin-spin splitting, I was hesitant to put a toe into these waters. But, as luck would have it, I had a brilliant undergraduate doing research with me, J. L. Beauchamp. This worthy zipped through the theoretical papers of Alexander and Kaplan and produced a working FORTRAN program for calculating lineshapes as a function of reaction rate for the AB system where A and B are exchanging intramolecularly with the equilibrium constant equal to unity. Beauchamp's work was vital to the success

of many of our rate projects and was greatly extended by Whitesides, as a Caltech graduate student, to the problem of the configurational stability of 3,3-dimethylbutyl (neohexyl) Grignard reagents (see *Organic Chemistry Applications*).²¹ A major problem in this work was to obtain lineshapes for the change of an A_2X_2 spin system with $J_{AX} = J_{A'X'}$ to one of the $AA'XX'$ variety with $J_{AX} \neq J_{A'X'}$.

These changes in lineshape were more complicated than the change of AB to A_2 , with which J. L. Beauchamp had dealt. Whitesides was able to show that the lineshapes could be simulated as the sum of the lineshapes of two invariant antisymmetric resonances and the averaging of two different AB spin systems. He worked through the density matrix formalism for relating lineshapes to exchange rates in his thesis, and this provided my own introduction to such matters. Later, I gave a lecture about its use at an Organic Reaction Mechanisms Conference, but it was not received with the same enthusiasm as my earlier talk to the same group about NMR in general. At least, Whitesides was willing to concede afterward that I had achieved a minor acquaintance with the subject.

Conformational equilibria and equilibrations occupied our attention for many years. An important role in investigating rotations around single bonds and conformational equilibrations of cyclic compounds was taken by B. L. Hawkins, who devised computer programs to deal with the more complicated lineshapes involved.²² The study of rotational barriers about C–C bonds gave information that I hoped would be useful to test a priori calculations of barrier heights along the lines pioneered by Westheimer and Mayer for rates of racemization of optically active biphenyl derivatives. In the best Westheimer manner, I was determined that this not be a semiempirical method, with parameters derived from a best fit to the existing experimental data, but obtained from spectroscopic force constants and gas-phase interaction potentials. The calculations were not easy at that early stage of computer usage and the best test cases seemed to be the various haloethanes for which we and others had obtained barriers. The calculations were largely stymied by difficulties in knowing how to deal with the electrostatic interactions inherent with the electronegative halogen atoms in this class of ethane derivatives. Nonetheless, I was emboldened to make the ethane rotation problem the subject of my Roger Adams Award address at the Organic Chemistry Symposium in 1967. I think it was an artistic triumph, but surely a crashing bore for most of the audience who were dragged through an exposition of principles without much of a take-home lesson of useful knowledge.

Our studies of conformational equilibria and equilibration in cyclic compounds were more successful—because others more talented had analyzed many of the ring systems in which we were interested and there was a large body of speculation that could be subject to experimental test. The problem presented by the complexity of the proton spectra in the slow exchange regime led us to label the various cycles with one or more CF_2 groups. Such labeling takes advantages of the much larger chemical shift differences of fluorine than hydrogen, but suffers from the disadvantage that few organic chemists are willing to accept the notion that the rates of inversion, or of any other processes, occurring with a fluorine-substituted cycle could even qualitatively reflect what happens with the parent hydrocarbon.

We already had our toes in the water of this pond, through J. B. Lambert's study of the changes in ^{19}F chemical shifts with

temperature of *gem*-fluoro-substituted cyclobutanes.²³ These results gave some idea of the torsional oscillations and the conformational preferences of cyclobutane rings.

K. Nagarajan found that 1,1-difluorocyclohexane at room temperature gave a simple quintet for its ^{19}F spectrum, as expected for an A_2X_4 system, but this is deceptively simple because each fluorine is not coupled equally to the hydrogens flanking it and the two-bond fluorine–fluorine coupling is large.²⁴ At $-100^\circ C$, an $ABX_2X'_2$ type spectrum was observed, with a 15.7-ppm fluorine chemical-shift difference and a fluorine–fluorine coupling of 237 Hz. The changes of lineshape with temperature gave an E_a value of about 11.5 kcal mol⁻¹, close to the 11.1 kcal mol⁻¹ found by Anet for cyclohexane itself, in support of our premise that the *gem*-fluoro compounds could be useful models for studying conformational equilibrations. J. T. Gerig made further progress on cyclohexane systems by a beautiful study of the conformational equilibration of *cis*-decalins.²⁵

The larger ring systems of cycloheptane, cyclooctane, and cyclodecane showed dramatically different behaviors, although those for cycloheptane and cyclodecane had been well predicted by Hendrickson and Prelog, respectively. Thus, 1,1-difluorocycloheptane displays no fluorine chemical-shift difference at as low as $-170^\circ C$, because the ring assumes a conformation where there is a favored C-2 site for *gem* substituents.²⁶ Cyclodecane has a favored *gem*-substitution site, but now with nonequivalent fluorines if ring inversion is slow as it is at below about $-135^\circ C$.²⁷

Cyclooctane is quite conformationally mobile and seems to exist in families of conformations of about equal energy. Interconversions are fast at room temperature and until about $-100^\circ C$, where an AB pattern emerges with a small chemical shift difference of 3.9 ppm and a fluorine–fluorine coupling of 245 Hz. Then, below $-150^\circ C$, this turns into two overlapping AB spectra with larger chemical-shift differences of 14.3 and 16.7 ppm.²⁸ Anet was later able to interpret our results by equilibrating chair-like conformations instead of the boat-like structures we had favored.

It is challenging to explain conformational equilibrations for larger rings than cyclohexane in lectures, and for a 1965 Organic Symposium talk at Arizona State University I used molecular models scaled to 1-m bond lengths with 6-in. balls for atoms. These were very unwieldy to handle, but fortunately J. T. Gerig was a most capable assistant in showing how larger rings can undergo equilibration.

To be truly useful, ^{13}C NMR has to be available at the natural-abundance level for at least medium concentrations of organic compounds. However, the signal-to-noise ratio obtainable with natural-abundance ^{13}C using the spectrometers of the 1960s was not favorable. P. C. Lauterbur employed rapid-passage, dispersion-mode procedures to show that natural-abundance ^{13}C had enormous potential for the determination of organic structures, but the technique sacrificed considerable resolution for gains in sensitivity. D. M. Grant and co-workers at Utah then made an important advance through using proton decoupling, but natural-abundance ^{13}C was still by no means routine. An important development in this period was the availability of computers of average transients (CAT) with which electronic signals could be digitized and time-averaged to improve the signal-to-noise ratios. However, the procedure is of limited value unless the spectrometer has good frequency stability, a characteristic missing from NMR spectrometers of

the early 1960s. Fortunately, I got an NIH grant to investigate how to contrive a spectrometer to obtain natural-abundance ^{13}C NMR in a routine fashion.

I was discouraged about knowing where to start, when I saw a Hewlett-Packard advertisement in the *Scientific American* for a digital-frequency synthesizer of extraordinary stability. Further, the synthesizer would change frequency in 0.01 Hz increments with a suitable voltage ramp. Because the frequency range was right for ^{13}C NMR, I put \$10 000 (in 1960ish dollars) on the line to get one in the hope that it would solve the stability problem that made long-term signal averaging difficult. I then contacted Varian Associates and suggested that perhaps they could build a ^{13}C spectrometer around the H-P synthesizer. Varian was not optimistic about the success of the project (suggesting that 'phase problems' would sink the ship) and I decided we would have to try to go it on our own.

A short time later, Varian management changed its mind and I put in an order for a digital frequency sweep spectrometer using my H-P synthesizer. The result was a true advance in NMR instrumentation with its excellent resolution for 10-mm diameter samples, frequency synthesizer, digital sweep programmer, field/frequency lock channel, and signal-averaging computer. The stability was superb and spectra could be taken over as long a period as desired. This was a spectrometer wholly dedicated to nuclei other than protons, because proton signals were used for the field/frequency lock at 60 MHz. The spectrometer was installed in late 1966, just in time for it to be taken over by F. J. Weigert, a new graduate student from MIT. An extraordinarily motivated and talented researcher, he cut a broad swath through many aspects of natural-abundance ^{13}C NMR. Weigert completed his Ph.D. thesis in just two years and eight months and produced 16 very substantial papers in the process. His first paper was concerned with the complex proton-coupled ^{13}C spectrum of benzene.²⁹ Some measure of the sensitivity achieved by the Varian engineers for the DFS spectrometer can be deduced from the fact that Weigert was the first to be able to measure ^{13}C – ^{13}C couplings at the natural abundance level.³⁰

As soon as ^{13}C NMR became relatively routine, there was pressure for the adoption of a reference substance as a frequency standard. Many substances had been proposed and we liked carbon disulfide, because it came near the low-field end of the common range of ^{13}C shifts. The Varian group was strong for tetramethylsilane (TMS) which is a good standard for both ^{13}C and proton NMR, except that, when its resonance is taken as zero, shielding constants become negative instead of positive. G. v. D. Tiers tried to solve this problem for protons with the τ scale and, while initially popular, it had awkward features and rather quickly faded from general use.

Natural-abundance ^{13}C NMR was not really routine until the introduction of broadband noise proton decoupling. Such decoupling removes the proton splittings from the ^{13}C resonances and, in addition, gives a favorable nuclear Overhauser effect (NOE). Thus, a proton-coupled doublet ^{13}C resonance, such as exhibited by trichloromethane, with broadband decoupling produces a singlet peak with a sixfold increase over the intensity of each of the individual doublets. There is hardly a better early example of the utility of broadband proton decoupling for ^{13}C spectra than for cholesterol.³¹ Weigert had found it impossible to make sense out of the 15-MHz coupled spectrum of cholesterol, because of the jumble of resonances and

the generally poor signal-to-noise ratio, even after hours of signal averaging. In contrast, with broadband proton decoupling, 25 rather well separated resonances were observed. A challenge was thus presented of spectral assignments and was met by H. Reich and M. Jautelat in about six months.³² An important element in the unraveling of the resonances was D. M. Grant's work on the steric influence of axial methyl groups on ^{13}C shifts in cyclohexane rings (see *Organic Chemistry Applications*).

With broadband proton decoupling, we were able to analyze the ^{13}C spectra of many natural products. Particularly notable was D. E. Dorman's study of sugars³³ and J. G. Nourse's Herculean effort with erythromycin antibiotics.³⁴ Another wonderful project was determining the degree of tacticity of the stereoisomers of polypropylene,³⁵ a subject that became of intense interest in law suits involving possible infringement of the Natta patents on isotactic polypropylene by a gaggle of large US corporations.

About 1970, it was clear that the pulse Fourier technique applied to NMR spectroscopy (FT NMR) by R. Ernst could give superior sensitivity compared with the frequency-sweep procedure we were using with our DFS spectrometer, except when quite narrow ranges of the spectra were to be studied. We were eager to become involved, but Varian was not enthusiastic about upgrading our, by now technically obsolete, DFS spectrometer. The company was enthusiastic about our paying to develop a ^{13}C FT NMR accessory for the 220-MHz instrument obtained for Caltech through the efforts of S. I. Chan, even though the 5-mm sample size available for that spectrometer was too small for reasonable signal-to-noise ratios. Nonetheless, we put in an order and a year later a unit was delivered and found to be of minimal usefulness. Varian said that it would be impossible to move the ^{13}C unit over to the DFS spectrometer, but two highly motivated postdoctoral fellows, B. L. Hawkins and J.-Y. Lallemand, with the help of C. Tanzer of Bruker Magnetics were able to do what needed to be done and, in 1973, we published our first papers using ^{13}C FT-NMR with the DFS unit on tetrahydrocannabinols³⁶ and Rauwolfia alkaloids.³⁷ Thus was born the first and only Brukerian pulse Fourier transform spectrometer.

Starting in the late 1940s, I had been deeply involved in the carbocationic rearrangements that so easily interconverted cyclopropylmethyl, cyclobutyl, and 3-butenyl derivatives. While we used NMR in various ways to determine structures and analyze product mixtures in this research, we had little hope of determining the nature of the C_4H_7^+ intermediate which was one of the central actors in the prolonged controversy over 'nonclassical' carbocations. Then, in 1965, G. A. Olah developed a procedure for generating stable solutions of carbocations in his 'magic acid' formulations and, furthermore, the proton and ^{13}C NMR spectra could be taken of the carbocations in solution. Applied to C_4H_7^+ , Olah found the proton spectrum to have only a single-proton high-field CH multiplet and two three-proton doublet resonances.³⁸ Because C_4H_7^+ should have one CH and three CH_2 groups, the carbocation has to possess nonequivalent methylene hydrogens with different couplings to the unique proton and are also not coupled to one another. That the protons on the separate methylene groups have the same chemical shifts must be the result of rapid equilibration of the methylenes, as we had earlier demonstrated by shuffling of carbon atoms in a number of typical carbocationic reactions. In the main, the

NMR spectra are not grossly different from what might be expected from $C_4H_7^+$ as an equilibrating mixture of nonplanar, unsymmetrical bicyclobutonium carbocations, much as we had postulated from chemical evidence earlier on. There is more to the story of NMR in study of the fascinating and unusual $C_4H_7^+$ cation (see *Organic Chemistry Applications*).

About 1963, we decided to look into ^{15}N NMR spectroscopy. For ^{14}N NMR, there are problems with large linewidths attendant to rapid quadrupole relaxation. On the other hand, while the ^{15}N nucleus has spin $\frac{1}{2}$, its natural abundance is only 0.31% and its magnetic moment only about one-tenth that of protons. At the natural-abundance level, ^{15}N NMR can be expected to have something like a millionth of the signal strength of protons for a substance containing equal numbers of nitrogen and hydrogen atoms. Nonetheless, useful spectra could be obtained from samples isotopically enriched in ^{15}N at 6 MHz with concentrations on the order of 1 M or more. The availability and expense of compounds enriched in ^{15}N made research in this area difficult. We found it expedient to start with a commercial sample, nitrobenzene labeled with ^{15}N , run its spectrum, then convert it to nitrosobenzene, run its spectrum, and so on. Use of this relay technique afforded the ^{15}N shifts of phenylhydroxylamine, azobenzene, azoxybenzene, hydrazobenzene, and aniline. The overall range of chemical shifts found by J. B. Lambert and G. Binsch covered some 900 ppm.³⁹

Our next project investigated whether a relationship existed between $^1J(^{13}C, ^{15}N)$ couplings and the 2s characters of the bonding orbitals, as had already been shown for $^1J(^{13}C, H)$ couplings. This required substances doubly-labeled in both ^{13}C and ^{15}N and G. Binsch undertook making 10 such compounds by the relay technique with verve and skill. The resulting $^1J(^{13}C, ^{15}N)$ values gave only a fair parallelism with the expected 2s orbital contributions to the C–N bonds.⁴⁰

Our DFS spectrometer could also be used with ^{15}N and F. Weigert apparently obtained the first natural-abundance ^{15}N spectrum of hydrazine in 1969. R. L. Lichter then developed conditions for taking ^{15}N spectra in a more routine way and, in particular, utilizing the proton decoupling for both simplifying the spectra by removing proton–nitrogen couplings and generating a very favorable, albeit negative, NOE. Under optimum conditions, where all of the ^{15}N relaxation results from dipolar interactions with neighboring protons, the negative signal is about four-times more intense than expected by just removing the proton splitting.

Lichter proved that there was a very close correlation between the ^{13}C shifts of hydrocarbons and primary and secondary amines, where the ^{13}C and ^{15}N are in analogous positions (see *Organic Chemistry Applications*).⁴¹ These studies were later greatly extended by R. Duthaler.⁴²

The sensitivity of the DFS spectrometer for ^{15}N was marginal, especially if the proton NOE was unfavorable. The accumulation times were long and ^{15}N NMR was going to require a single-purpose spectrometer if many ^{15}N spectra were to be taken. A higher field was expected to help greatly with the sensitivity problem. I was able to raise \$150 000 from the NIH to purchase a dedicated high-field ^{15}N spectrometer, and a difficult period ensued while the instrument companies blew hot and cold on giving us a quotation within our budget. Varian wanted to use our funds to develop a 300-MHz proton spectrometer with a ^{15}N probe using 10-mm diameter sample tubes for \$366 000. Obviously this was out of our price range,

and we actually did not want the proton capability, because this would mean that we would surely get requests to use the spectrometer for proton spectra. Bruker's quote was also out of range with a proposal for a 270-MHz proton spectrometer with a ^{15}N probe for \$300 000.

As is customary in such cases, we strived to get Varian and Bruker to compete to build the instrument and also limit it to ^{15}N and possibly ^{13}C capability. Finally, we were rescued by D. M. Grant of the University of Utah who proposed that we opt for a lower magnetic field, but larger samples. 'A milk bottle if necessary.' Grant's argument was that a larger sample could gain more sensitivity than a higher field, because a 30-mm sample tube might well contain 10–30-times more sample in the active volume of the coil. Furthermore, he recognized that because the resonance frequency of ^{15}N was smaller by a factor of 10 than that of protons, the requirements for a given level of resolution would be much less stringent than for protons. This concept led to a new competition between Varian and Bruker and now Bruker won with an offer of a 15-MHz ^{15}N spectrometer with 25-mm tubes for \$131 500.

Our Bruker order turned out not to have a very high priority within the company and it was not until mid-1974 that Bruker's C. Bradley started with the console of a Bruker WH-90 spectrometer, doubled its frequency to 180 MHz for the proton decoupling channel, and built ^{15}N and ^{13}C probes operating at 18 MHz and 45 MHz, respectively. The electronics embodied quadrature detection, which was new at the time, and the magnet was a superconducting solenoid with a 3-in. bore. The so-called WH-180 worked wonderfully well, with excellent resolution and sufficient stability to allow spectra to be time averaged over as long as 72 h. However, being custom-built, it was bereft of instruction manuals and had minimal documentation of the differences between its electronics and those of its WH-90 predecessor. It seems a fact of life, if you push for a custom-built spectrometer, the builder assumes that because you are smart enough to know what you want, you must be smart enough to get along without a lot, or even any, hand-holding in operations and maintenance.

The sample volumes were on the order of 18 mL and to get useful spectra in just a few hours the concentrations had to be about 1 M in nitrogen. When biochemists would ask us if we could take a ^{15}N spectrum for them, they blanched and quickly departed when they heard how much material we needed to run spectra of enzymes or other high molecular-weight substances at the natural abundance level of ^{15}N . Nonetheless, R. Moon and D. Gust were able to get good natural-abundance ^{15}N spectra of substances such as vitamin B₁₂, lysozyme, trypsin, salmonine, and yeast tRNA.⁴³ These compounds were not only available in substantial quantities but also, up to a point, the T_1 value of ^{15}N becomes shorter as the molecular weight increases and this allows for improved rates of signal averaging through more rapid pulsing. The success of the WH-180 vindicated Grant's concept of large sample sizes and demonstrated the utility of ^{15}N NMR for medium molecular-weight biochemically interesting compounds.

Much of our research on ^{15}N NMR was aimed at obtaining an understanding of how the spectra are influenced by the chemical surroundings of ^{15}N as exemplified by chemical shifts, coupling constants, and T_1 relaxation rates, as well as rates of chemical exchange. Another focus has been on showing how ^{15}N NMR can be used to examine the active

sites of enzymes, pathways of nitrogen metabolism, and environments within living cells.

A particularly effective use of ^{15}N is where the nitrogens of interest form double or triple bonds and, in addition, possess an unshared electron pair. Pyridine is a good example and its ^{15}N spectrum shows about 85–100 ppm shift to higher magnetic fields on accepting a proton.⁴⁴ Even hydrogen bonding to the pyridine nitrogen can cause shifts of up to 35 ppm.⁴⁴ We were able to use such changes in shift of nitrogens in $\text{C}=\text{N}$: groupings to establish the preferred site of protonation of vitamin B_1 ,⁴⁵ as well as of nucleosides and nucleotides.⁴⁶

The most dramatic of our research on enzymes was on the base strength and position of the N–H tautomeric equilibrium for the histidine at the active site triad of serine proteases. It had been postulated by D. Blow from his excellent crystal structure of α -chymotrypsin that the so-called catalytic triad of serine, histidine, and aspartic acid residues acted in concert to assist the hydrolysis of peptide bonds. A small serine protease, α -lytic protease, with a single histidine, had been suggested to favor this hypothesis through an abnormal histidine base strength determined by analysis of ^{13}C chemical-shift changes found to occur with changes in pH.

W. W. Bachovchin undertook a reinvestigation of this enzyme labeled at its histidine with ^{15}N .⁴⁷ To do this he generated a myxobacter mutant for which histidine is an essential amino acid and, through extraordinarily careful experimentation, was able to grow the mutant on very expensive ^{15}N -labeled histidine and isolate the desired labeled α -lytic protease. The changes in the chemical shifts of the histidine nitrogens with pH showed that the pK_α value of the histidine was quite normal. We could also infer that there seemed to be significant hydrogen bonding of the protonated histamine, most probably to the aspartate carboxylate. Finally, there was strong evidence that the N–H tautomeric equilibrium was shifted from the usual position with the hydrogen most favorably located on N-1 to predominance for location at N-3, again through probable hydrogen bonding to the aspartate carboxylate. Bachovchin's results supported a very rational formulation of the catalytic triad.

With the help of K. Kanamori, a collaboration was achieved with B. Vallee and Bachovchin, by then a postdoctoral fellow at Harvard Medical School. At issue was the spatial location of a presumed active-site tyrosine of carboxypeptidase. Was it normally complexed with active-site zinc atom in the native enzyme, or did it move up to the zinc only when the enzyme was complexed with a substrate or inhibitor? Kanamori studied the ^{15}N shift changes with pH of the enzyme to which a ^{15}N -labeled azoarsanilic group had been coupled to the tyrosine in question.⁴⁸ The ^{15}N NMR results seemed to show that the degree of complexation was pH-dependent, and evidence was obtained of zinc binding at the higher pH values, but not at lower pHs. Substantial effort was required to elucidate the zinc–tyrosine binding, but it was later shown that the particular tyrosine residue was not needed at all for carboxypeptidase to be catalytically active.

N. Becker used ^{15}N NMR to study pyrazole inhibition of the zinc-containing enzyme, liver alcohol dehydrogenase (LAD).⁴⁹ This enzyme has a molecular weight of about 80 000 and we found that the ^{15}N resonances of both ^{15}N -labeled pyrazole and ^{15}N -labeled *N*-nicotinamide-adenine dinucleotide, NAD^+ , mixed with LAD gave quite sharp resonance lines. The complexed entities were clearly well bonded to the LAD

because they were not removed by dialysis. The upshot of Becker's research was to show that pyrazole became complexed to both the zinc and the NAD^+ , as well as showing that quite high molecular weight substances could be studied by ^{15}N NMR, provided that they are reasonably conformationally flexible.

About 1980, K. Kanamori started a collaboration with R. Weiss and T. Legerton of UCLA on the pathways of nitrogen metabolism of *Neurospora* molds with ^{15}N NMR.⁵⁰ At the outset, this project did not look very hopeful to me from the standpoint of sensitivity and of possible line broadening through complexations or viscosity problems within the cells. Kanamori quickly showed that *Neurospora* fed on ^{15}N -enriched ammonium salts, converted the starting material to glutamate or glutamine, and throughout the resonance lines of the products were sharp, as well as coming from the substances within, not without, the cells. With moderate levels of ^{15}N , spectra could be obtained quickly and the growth and metabolism of *Neurospora* could be studied right within the spectrometer. Kanamori also investigated the ^{15}N NMR shift and relaxation properties of several intracellular amino acids in *Neurospora*.⁵¹ These amino acids appear to become sequestered in vacuoles within the cell and these vacuoles are at different pH values and the amino acids have mobilities less than they have in the cytoplasm.

A fascinating and rewarding ^{15}N project arose in the course an investigation of which of the two natural-abundance ^{15}N resonances of diazocyclopentadiene arises from which nitrogen. For this, we synthesized the compound labeled with ^{15}N at the nitrogen closest to the ring by the reaction of cyclopentadiene anion with ^{15}N -labeled toluenesulfonyl azide (TsNN^{15}N). Some rearrangement occurred and part of the diazocyclopentadiene was found from the NMR to be labeled at the terminal nitrogen. This was investigated by C. Casewit who found that the rearrangement in question involved a reaction of TsNN^{15}N and the unlabeled anion of toluenesulfonamide (TsNH^-) to yield Ts^{15}NNN .⁵² Furthermore, at least 10 other resonances of ^{15}N -labeled substances were observed, even though the only labeled starting material was TsNN^{15}N . The products identified by NMR were $^{15}\text{NNN}^-$ and N^{15}NN^- , $\text{Ts}^{15}\text{NH}^-$, ^{15}NN , TsN^{15}NN , Ts^{15}NNN , $\text{Ts}_2^{15}\text{N}^-$, $\text{TsN}^{15}\text{NNTs}^-$, and $\text{Ts}^{15}\text{NNNTs}^-$. The information of dinitrogen was intriguing, because it seemed best formed from N_6 which would arise from coupling of TsNNN with NNN^- and elimination of Ts^- . Formation of Ts^- was indeed indicated by the presence of TsNNNTs^- formed by Ts^- addition to TsNNN . Did linear N_6 cyclize to hexaazabenzene and then decompose to give 3N_2 ? Unfortunately, we could not devise an experiment that would prove or disprove that possibility.

About 1984, I decided to look into NMR imaging or MRI as it is now called. An opportunity to undertake such research was available at the Huntington Medical Research Institutes (HMRI) in Pasadena, which had acquired one of the first commercial MR imaging units in the world for the use of W. G. Bradley, a very productive clinical MRI researcher. The contrast scale of MRI is primarily determined by chemistry and it seemed like a natural for study by an organic chemist interested in NMR. We did do imaging experiments on solvent swelling of polymers, but it was a difficult research situation because the imager was heavily scheduled for clinical work and each hour given to our work cost several hundred dollars of clinical revenue. The need for medical emergency scans

sometimes meant that the imaging personnel were shifting from one foot to another waiting for us to finish up our work.

When I 'graduated' to the status of Emeritus Professor in 1988, the then current rules of the California Institute of Technology precluded the operation of a graduate or postdoctoral research program. In principle, all that was allowed was whatever research you could do with your own hands, in whatever space the administration would allow you to function. Wanting to continue NMR research at some level, I decided to test the waters by taking on undergraduate research students. Fortunately, the Institute responded favorably and we have completed several projects. One was concerned with improving ^{15}N signal-to-noise ratios by decreasing T_1 while still maintaining a favorable proton–nitrogen NOE.⁵³ Another had to do with the T_2 dependence of the water in oxygenated and deoxygenated blood as a function of hematocrit, clotting, and magnetic field.⁵⁴ Still another involved determining the rotational barrier about the C–N bonds of urea.⁵⁵

Most of our efforts have, however, been directed to determination of the influence of hydrogen bonding and electrostatic effects on conformational equilibria in ethane and propane derivatives, particularly in water solution (see *Organic Chemistry Applications*).⁵⁶ Along with these research projects, I have written a third textbook, 'Notes on FT-NMR'.

NMR has always been for me the endless frontier—a steady stream of new developments of increasing sophistication and of usefulness. It has been an unending thrill to be able to participate in its growth from near its beginnings.

UCLA, 1944–45; Harvard University, 1945–46; MIT, 1946–53; California Institute of Technology, 1953–present. Approx. 485 publications and 9 books. Research interests include physical organic chemistry and applications of NMR to organic chemistry, particularly the determination of conformational equilibria and conformational equilibration, as well as of ^{15}N NMR to problems in biology and medicine.

Rogers, Emery H.: Remembrance of NMR Things Past

Emery H. Rogers

Formerly, Varian Associates, CA,

Compared with humankind's Stone Age, in which hand-tool invention is obscured in the cobwebs of time, the arrival of nuclear magnetic resonance occurred just yesterday. Thanks to development-time compression, many original NMR cave dwellers are still here to provide reminiscences about how it started and why it engendered such extraordinary dedication and creativity.

It all began for us in California during that period of dynamic rejuvenation at the Stanford University Physics Department following the cessation of World War II, when many government laboratories were yielding experienced professors and degree-seeking students back to academia.

Immediately after my return to Stanford in January 1946 from the Naval Research Laboratory to pursue a physics doctorate, Martin Packard showed me my first proton 'nuclear induction' signal, quite impressive even in a tossing sea of noise. The image then was of *induced* signals from tiny precessing gyromagnets, rather than of stimulated quantum energy state transitions. This approach made it possible to ascertain, beyond admittedly improbable doubt, the absolute signs of the proton and neutron magnetic moments. Professor Hans Staub, a close associate of Professor Felix Bloch, asked me to join him in using nuclear induction along with related polarized neutron cyclotron beam techniques to make these sign determinations experimentally. Although this was quite unpredictable at the time, the ultimate definitive consequences of these obscure events led eventually to my joining the spirited effort to establish a new commercially available analytical method.

Because the creaky cyclotron in the Stanford basement had a frustrating tendency to blow a bulky fuse during the necessarily lengthy neutron runs, a solid copper bar was substituted temporarily for the offending component one memorable day. The electrical power lines to the Physics Department passed under the nearby Law School lecture hall. Several dozen law students, including possibly one or more of today's US Supreme Court justices, never discovered the origin of the rising smoke wisps which briefly sent them scurrying outdoors.

With the signs of the magnetic moments of the proton and neutron safely confirmed in 1949, the time had arrived for pursuing a career. Proving once again that the right person in the right place at the right time can move mountains, Russell Varian became the inspiring answer to our hopes and dreams. He, his brother Sigurd, and several others, had founded Varian Associates in 1948 on a back street in nearby San Carlos. With remarkable clairvoyance, Russ had decided that nuclear induction should be explored and developed within his fledgling klystron company, even though no commercial applications beyond magnetic field measurement then appeared promising. A number of us in the Stanford group, including Packard, Wes Anderson, Jim Arnold, Elliott Levinthal, Warren

Proctor, and Harry Weaver, joined Varian during the startup period. The effort to make NMR available somehow to the larger scientific community had begun.

Our first product was a fluxmeter which featured a nuclear induction probe on the end of a flexible cable. Having just emerged from academia, we had to learn how to achieve economies of scale by buying parts and building units in quantity—no mean accomplishment in an enterprise dedicated originally to contract research. We quickly discovered that magnetic field measurement had a rather limited market. Salvation soon arrived, however, in two forms: stand-alone electromagnet systems; and high-resolution NMR spectrometers for *chemists*, a heretofore exotic species to us physicists. The former market arose because of magnetic resonance and ferromagnetism research needs, and the latter arrived dramatically when Arnold, Dharmatti, and Packard saw the majestic three peaks of ethyl alcohol. At this fortuitous instant, Jim Shoolery, a bona fide chemist fresh from his CalTech Ph.D., and eager to lead us across the cultural divide into the promised land of NMR chemical applications, appeared at Varian's front door. Funded mainly by commercial sales of off-the-shelf magnet systems, and galvanized by the unswerving support of Russ Varian, our little team was now on a clear path.

A first major technical challenge was the compelling necessity to achieve much more stable and homogeneous magnetic fields. For several reasons, including flexibility, we chose electromagnets rather than permanent magnets for high-resolution NMR. My early work included shimming many magnets and designing a stable power supply to provide substantial direct currents for the water-cooled magnet coils. A mechanical 'chopper' converted dc error signals to ac for amplification, and then back to dc for correction, while an awesome array of eight glowing Eimac 304TL power transmitter tubes handled the stabilized output current.

Thin metal shims, shaped pole caps and adjustable ring shims helped open up improved volumes of magnetic field homogeneity. Remaining uniformity limitations were then surmounted dramatically by spinning the NMR sample rapidly, an ingenious technique which deceived the observed nuclei into 'seeing' a much more uniform average field. Greatly improved field stability arrived with a clever degenerative feedback coil system, developed for Varian by resident wizard Forrest Nelson.

The continuing story of how NMR was then taken from these developing conditions to standard analytical tool status has been related eloquently elsewhere (see, for example, J. N. Shoolery, *Anal. Chem.*, 1993, **65**, 731A). However, two specific personal memories about motivation and nomenclature are perhaps not superfluous here.

One day in 1957, Jim Shoolery and I visited the laboratories of a prominent East Coast chemical company. We took silent note of a wall placard which proudly proclaimed that infrared spectroscopy was the single most definitive analytical technique in existence. On the flight back to California, we were resolutely inspired to generate specifications for what would eventually become the widely successful Varian A-60 high-resolution NMR spectrometer.

Before this watershed time, we had encountered puzzling delays in export licence issuance for our first overseas nuclear magnetic resonance shipments. The mystery vanished when we found that export officials were needlessly alarmed by the

adjective ‘nuclear’, which to them always sounded ominous no matter how harmless the pertinent specific technology. We promptly sat down at a Varian cafeteria table and created the unsophisticated acronym ‘NMR’.

Decades later, the medical profession also concluded that ‘magnetic resonance imaging’—‘MRI’—is more palatable than ‘*Nuclear* magnetic resonance imaging’. If this particular writer is rolled into an MRI machine someday, it will be personally fascinating to observe a nuclear-radiation-free magnet gap up close from the inside rather than from the outside.

Saika, A.: Early Applications of NMR in Chemistry and Theoretical Calculations of NMR Parameters Related to the Electronic Structure of Molecules

A. Saika

Kyoto University, Kyoto, Japan

I started working in NMR in 1951 with Professor H. S. Gutowsky at the University of Illinois. At that time NMR was in such an early stage of development that I only needed to read a review article by Pake¹ as a preliminary study of the field. I was fortunate in that I did not need to survey such a formidable bulk of literature as has accumulated up to the present time.

I was first interested in applying Ramsey's theory² of nuclear magnetic shielding to interpret the fluorine chemical shift data by Gutowsky and Hoffman.³ However, the task of evaluating the excitation energies appearing in the perturbation theory by Ramsey seemed time-consuming in those days of desk calculators. So Gutowsky suggested observation of the proton resonances of acid solutions as an alternative. At the time I had no idea at all whether single or double peaks would be observed, but observation revealed only a 'single' peak! This results from fast exchange between the protons of the hydronium ions and water molecules. The effect of chemical exchange on the lineshape was obtained by including the chemical shift between the different chemical species in the Bloch equations⁴ for nuclear magnetization. The analysis enabled us to evaluate the apparent degrees of dissociation for various acids and alkalis.⁵ This NMR method of lineshape analysis opened up a new means of studying rate processes ranging between 10^{-2} and 10^{-4} s which are not readily accessible by other spectroscopic methods.

Following the work on the dissociation of electrolytes, Lee Meyer and I started to record the proton spectra of simple organic molecules, gathering our samples largely from the organic storeroom and laboratories at the university. During the course of these measurements it became clear that the chemical shifts for each particular proton type ranged over certain distinct bounded shift values. Thus, a graphical presentation⁶ of the shift ranges for various proton types serves as a guide map of proton shifts for structural analysis. This map, together with the simple proportionality of the relative absorption intensities to the numbers of nonequivalent protons plus the absorption multiplets due to nuclear spin-spin coupling, has saved considerably the labor in identifying the intermediate and final products obtained in the course of organic syntheses.

Nevertheless, my original plan to account for the much wider range of 10^{-3} of fluorine shift values compared with the proton shift range of 10^{-5} remained to be done. Following

the suggestion by Professor C. P. Slichter in the Physics Department that p-electrons must be the cause of such large shifts, I left the diamagnetic term entirely out of my considerations. Furthermore, by neglecting the paramagnetic term arising from other atoms which falls off as $1/r^3$, the problem was reduced to an atomic one. In this model, one p electron is considered to be missing from the closed shell of a covalently bonded fluorine. In order to avoid the difficulties in calculating the above-mentioned excitation energy, I had recourse to a plausible experimental excitation energy. This led to a large paramagnetic shift of -20×10^{-4} , in order-of-magnitude agreement with experiment. On the other hand, the paramagnetic term vanished for a completely ionic F having a filled shell. This paramagnetic shift difference, dependent upon the fraction of unbalanced p electrons on the fluorine atom in question, provided an explanation for its almost linear dependence on the ionic character of the bond.⁷ Such considerations may also be generally applicable to molecules with d valence electrons.

After returning to Kyoto University, my main concern turned to the more difficult problem of the theory of nuclear spin-spin coupling. In the early days, Ramsey, followed by many others, resorted to a 'mean excitation energy' approximation in the perturbation expansion. Since the numerator changed sign for each excitation, however, this gave erroneous results. When account of only the lowest excited states was taken, the results appeared to be reasonable. We then extended the procedure to include higher excited states, but no sense of convergence was noted.⁸ At this stage, I felt that electron correlation in nuclear spin-spin coupling was particularly important, and so I chose to employ a many-body perturbation theory (MBPT) with the aid of Feynman diagrams as a means of systematically incorporating correlation corrections order-by-order. The Fermi contact contribution up to second order in correlation in the HD molecule was calculated to be 28.1 Hz, as compared to the best estimate of 40 Hz.⁹ The result was still far from convergence, suggesting that perturbation of the external field (due to nuclear spins in the present case) is also significant. For this reason, I tried the finite-field (FF) MBPT to examine the validity of this scheme and obtained a value of 37.2 Hz in fair agreement with the best estimate.¹⁰ Thus, this approach, incorporating both electron correlation and field perturbation simultaneously, appears promising and appealing.

Finally, a brief remark should be added on nuclear magnetic shielding. By applying MBPT to shielding, we found that electron correlation is not important in this case, i.e., the coupled Hartree-Fock method affords results in quantitative agreement with experiment,¹¹ almost 30 years after our previous qualitative model.⁷ However, the latter gave a much more transparent insight into nuclear magnetic shielding! This brings back the thought that the noncomputer age still had certain merits.

Samoson, Ago: Development of High-Resolution NMR of Quadrupole Nuclei in Solids

Ago Samoson

Estonian Academy of Sciences, Tallinn, Estonia

Our NMR laboratory in Tallinn, established by Prof. E. Lippmaa, has been active in high-resolution solid state NMR since the mid-1970s. Some of the very first CP MAS ^{13}C spectra were run on a homebuilt spectrometer with an original double bearing spinner system. Typical rotation speeds were limited to a few kHz by the strength or expansion of the rotor material. The method was applicable to spin- $\frac{1}{2}$ nuclei and produced important analytical results, for example neat regularities between the structures of silicates and aluminosilicates and ^{29}Si chemical shifts.^{1,2} One of our collaborators, Dr. G. Engelhardt from Berlin, insisted on complementing the studies with those of ^{27}Al , as aluminum atoms may occupy various crystallographic positions.

The ^{27}Al nucleus has spin- $\frac{5}{2}$ and is subjected to electric quadrupole interactions, both first and second order. The possibility of averaging the first-order quadrupole interactions was demonstrated for ^2H NMR by Ackerman, Eckman, and Pines in Berkeley, using a conical single-bearing spinner.³ Averaging a first-order quadrupole interaction needs extremely precise spinning angle setting and more stable results were achieved with a double-bearing spinner system by the late M. Alla from our laboratory while working in Berkeley.⁴

Nuclei with half-integral spin $I > 1$ generally exhibit lines from $2I + 1$ transitions with the special property that the central transition is only shifted in second order. Although analysis of the second-order effects employing MAS had not been published, the first ^{27}Al spectra recorded in (East) Germany were encouraging in that they showed two lines, which were assigned to the tetrahedral and octahedral positions of the atoms in the structure.^{5,6} We were able to demonstrate, both experimentally and analytically, powder pattern lineshapes of the second-order quadrupole interaction under conditions of fast spinning at 54.7° to the magnetic field.^{7,8} Very similar results were reported shortly afterwards by several other NMR groups.^{9–11}

While running spectra on various materials we frequently noticed that a 180° pulse was not achieved. A remark by C. Alma-Zeestraten from Amsterdam about difficulties with 270° pulses triggered a suspicion of a more fundamental cause—the process of excitation of a central transition signal is not as straightforward as in the case of a spin- $\frac{1}{2}$ nucleus. Consideration of first-order quadrupole interaction during the rf excitation pulse immediately explained all the anomalies.¹² A systematic extension of the pulse length provides for 2D nutation spectroscopy with a potential of estimating the quadrupole interaction value.¹³ This value is needed for a correct interpretation of the field-dependent line shifts in the spectra. Two-dimensional spectroscopy also helped to reveal a missing component in the ^{27}Al spectra of dehydrated

zeolites,¹⁴ and to determine the relative orientations of chemical shielding and quadrupole interaction.¹⁵

Meanwhile, new materials, suitable for rotors, had become available. In 1984, due to our skilful machinist A. Salumäe and crucial design improvements by Dr. M. Alla, we were able to spin samples above 17 kHz. However, the machineable ceramic Macor contained aluminum and for work on aluminosilicates we had to use polymers. The new three-dimensionally cross-linked polymer Vespel allowed speeds of up to 8 kHz, which was a big improvement and facilitated the observation of satellite transitions.^{16,17} This method is of benefit for $I = \frac{5}{2}$ and $I = \frac{9}{2}$ nuclei, as one of the transitions features very low residual second-order quadrupolar line broadening. In addition, the narrow line in spin- $\frac{5}{2}$ spectra is very close to the actual chemical shift value and is thus little affected by the ubiquitous dispersion of quadrupole interactions. A combination of fast MAS, nutation, and satellite transition spectroscopy enabled us to measure the chemical shift of ^{27}Al with a precision comparable that of ^{29}Si . Not surprisingly, almost identical shift correlations with the structural features were established for both atoms in aluminosilicates.¹⁸

The combination of MAS with nutation was somewhat phenomenological and a brief analysis was presented whereby we also proposed a quadrature nutation using a soft pulse after evolution.¹⁹ Although our analytical description was met with some criticism by developers of multipole operators,²⁰ the fictitious spin formalism used by us offers advantages for one obvious reason: the observable signal is proportional to just one of the operators.

Pines and his students at Berkeley had noticed that spinning at certain angles produces frequency reversed powder patterns. This observation led them to the idea of refocusing the second-order interaction by switching the spinning axis.²¹ A systematic increment of evolution time, fractioned to spinning at different angles, produces stick spectra on a parametric axis.

High-resolution spectra in real time require repeated reorientation of the sample at a rate which is fast compared with homogeneous line broadening. Any pertinent reorientation scheme, which would of necessity be more sophisticated than simple rotation about one axis, also had to be feasible mechanically. Conical reorientation instead of a robust tilt of the rotation angle seemed one such possibility and, with a suitable choice of angles and speeds, it was easy to verify that spinning around two axes would create the necessary effect.²² The same idea was simultaneously forwarded by Llor and Virlet in Saclay.²³ The first attempt at mechanical implementation was derived from the observation that single-bearing conical rotors tended to wobble while spinning. A rotor with a spherical bottom was constructed in the hope that the wobbling would be amplified but the conical motion generated was disappointingly slow and at about 10 Hz the rotors became detached from the stator. Better guidance of the rotor could be achieved using a double bearing and axial support. However, the centripetal or gyroscopic forces would easily exceed the load bearing capacity unless they were opposite and equal. Such forces generally depend on both the shape of the moving body and the trajectory of the motion. The whole project started to look much more feasible after we realized that the dimensions of a cylindrical body performing the required motion are actually quite reasonable: the ratio of the length to the diameter is ca. 3. This triggered the construction of a double rotor system.²⁴ The outer

rotor of a prototype unit, machined with great patience by C. Gaskins at the Chemistry Department machine shop in Berkeley, spun up to 400 Hz, after few modifications, which was sufficient to demonstrate real-time averaging of the second-order quadrupole interactions.

Further major enhancements to the technique were related to sideband suppression. As opposed to regular MAS, outer rotation objects are characterized by a random interaction strength but not a random orientation. Synchronization of an excitation pulse with the outer rotor phase gives a certain degree of control over the sidebands. The number of sidebands can immediately be reduced twofold²⁵ and by a factor of four using two inversion pulses.²⁶ Another peculiar feature of DOR, caused by the orientation of the sample, is the dependence of sideband broadening on the spinning angle of the outer rotor.²⁷

The number of applications using DOR is not very great to date. The method requires expensive probes and trained operators. However, with outer rotor speeds above 1000 Hz, and using sideband suppression, DOR has proven useful for the study of glasses, cements, catalysts, and other industrially important materials.^{28–31}

Current NMR probe designs, enabling speeds four-times higher than the speed of the DOR prototype, and over 25 kHz MAS, are based on 20 years experience of high-speed rotor development in our laboratory. Although standard machine shop facilities do not guarantee the necessary precision, the prohibitive costs of special equipment have been substituted by the qualifications and devotion of our technicians A. Reinhold and T. Anupöld.

Human curiosity and experience, advances in high-performance materials, and the momentum given by possible analytical applications have generated a new branch of NMR spectroscopy—high-resolution solid state NMR of quadrupole nuclei. This method combines quantum, classical, and machine shop mechanics, at a level which is sophisticated even for each separately. Members of our group have been fortunate to participate in this development and we hope that our contributions will form the basis for further exciting advances.

Sanders, Jeremy K. M.: Luck, Ignorance, and Daring in Research: NMR Spectroscopy of Nature's Plastics and Spiders' Webs

Jeremy K. M. Sanders

University of Cambridge, Cambridge, UK

Do scientists always set out with a well-defined question and proceed to solve it logically? Some do, but in my experience, accidental discoveries, wrong conclusions, and outrageous experiments are also a good way of undertaking science. One episode in our biological NMR work makes the point—it is described in more detail elsewhere.¹

In the early 1980s, we began using solution state NMR experiments to study the metabolism of small molecules in live bacteria. By adding ¹³C- or deuterium-labeled substrates to suspensions of live cells we were able to see the biochemistry that interested us without interference from the hundreds of natural-abundance components present within the cell. These background signals were insignificant in most species. However, in 1986, my student Glenn Barnard found that the spectra of *Methylobacterium* species were dominated by natural abundance signals from within the cell. In particular, one compound with just four signals was present in highly variable amounts; its identity remained a mystery for a few weeks until, browsing in the library, I came across a paper by Jake Schaefer² describing the solid state NMR spectrum of polyhydroxybutyrate (PHB). The shifts matched almost perfectly. PHB is a bacterial storage polymer of molecular weight around a million, stored as submicron-sized granules; the isolated polymer is a commercially available biodegradable plastic. Having stumbled across PHB in these cells, we became fascinated: NMR was a new window into the biological and physical chemistry of PHB.

Solids do not usually give high-resolution spectra when solution state techniques are applied; their signals are too broad to be observed by such methods. In 1986, the conventional wisdom was that PHB in granules is a crystalline solid, so the observation of PHB in live cells using solution state NMR was very surprising. Indeed we were successful only because we were ignorant of conventional wisdom. However, the use of solution state NMR techniques, including relaxation experiments, allowed us to show that PHB within the granule is an elastomer, not crystalline as was generally believed.

It had long been recognized that PHB granules have paradoxical properties, many of which were resolved by this insight, but our results raised new problems: how does the cell prevent PHB crystallization in vivo and what triggers crystallization when the granules are isolated? For some years, we and others searched for plasticizers or nucleation inhibitors within the granule, while freeze-drying results suggested that water also plays a role. All this searching was in vain—nobody found any positive evidence. We then realized that the explanation is much simpler: the maximum rate of spontaneous

crystal nucleation found for pure isolated PHB is less than 10^2 events $\text{mm}^{-3} \text{s}^{-1}$. The volume of an individual native granule is around 10^{-10}mm^3 , so the nucleation rate *per granule* is less than 10^{-8} events s^{-1} and the average lifetime of a native granule before crystallization will exceed 10^8 s, i.e. years. Cells store PHB in a thermodynamically unfavorable state simply because the crystallization kinetics are so slow. If this model is correct, then we should be able to reproduce it in the laboratory, and indeed Daniel Horowitz in my laboratory has done so with great success.³ It appears that after many twists, turns, and false trails we now have a reasonable working model of the granule interior; fortunately, one of the false trails led us in an unexpected direction—spiders' webs.

Just when we were convinced that water is involved in plasticizing PHB, a paper appeared on the role of water in maintaining elasticity in spiders' webs. The coated capture threads in the web of the common garden spider stretch by up to 400% when absorbing the momentum of a captured flying insect, whereas the structural thread which the spider builds as a rigid scaffolding is barely elastic at all. What is the difference between these threads and how can such elasticity be explained at a molecular level? Either some part of the protein is flexible and acts like a spring, or rigid rods slide past each other as in muscle contraction; in each case water is supposed to act as plasticizer or lubricant. Flexible springs should give high-resolution solution state spectra, while rigid rods would not. Fortunately, Fritz Vollrath agreed to provide suitable web samples. Each web weighs only around 1 mg, and so around 20 capture or structural webs from captive spiders were collected and wound onto a glass capillary, but sensitivity and sample size limited the quality of spectrum: we needed ¹³C-labeled webs. Captive spiders generally live on fruit flies but Vollrath was able to feed them directly with solutions of ¹³C-labeled glucose or amino acids. Webs containing only structural threads were collected, and then whole webs containing capture and structural threads were separately collected from the same spiders.

The crucial observation was that, in the presence of water, the capture web has regions which are mobile on the NMR timescale; the spring mechanism was vindicated. Structural threads give no high-resolution signals under the same conditions. They lack molecular mobility or elasticity, even in water, and must have a different arrangement at the molecular level.

Our first breakthrough in understanding PHB granules in 1986 came about accidentally. Nobody who 'knew' that PHB is crystalline in vivo would have attempted our experiment, and nobody could have got a grant to do the work. Our spider work happened because we mistakenly believed that water was a plasticizer for PHB and drew an incorrect analogy.

So how should we do science? One can choose a big problem, lay a plan, obtain funding and people, and solve it; or one can set out to explore a trivial byway while keeping eyes and mind open. The first approach is a vital component of science—the second can be more fun.

Saunders, Martin: The First NMR Spectrum of a Protein

Martin Saunders

Yale University, New Haven, CT, USA

When I started teaching at Yale in 1955, there was no NMR spectrometer at the university. In the next year, the Chemistry Department decided to buy one. No one else on our faculty wanted to be associated with it; so, as the most junior member, I was assigned the task of setting it up, operating and maintaining it, and (if possible) finding something to do with it. Our instrument was a 40 MHz Varian spectrometer for protons only, with no field/frequency lock and an electromagnet cooled by city water. The temperature of the water changed with the season, requiring that the magnet be 'shimmed' using an 8 ft. pipe on a wrench on one of the bolts fastening the pole pieces and with all my weight on the end of the pipe.

The Head of the Department, John Kirkwood, was very interested in the physical chemistry of proteins. One day, he asked me what one could learn about proteins with this new instrument. I told him that I did not know but that I would find out. I asked people in the department for a sample of some protein and was given a small amount of ribonuclease. When I looked at an aqueous solution of it, at first I saw nothing but a strong water signal. After shimming the field, increasing the gain, and sweeping more slowly, I eventually saw a tiny peak on the upfield side of the water peak (conceivably due to the protein). Since the water protons were interfering with the observation of the protein signal, the next step was to dissolve the protein in D₂O instead of water. Now it was clear that a definite signal was produced. However, there was still a very large water peak obscuring part of the spectrum. We decided that this resulted from the water of crystallization and exchangeable protons. At this point Arnold Wishnia, who was a Kirkwood postdoctoral, joined the project. Arnold lyophilized the D₂O solution and dissolved the solid protein in fresh D₂O. When this was repeated several times, the water peak was reduced and the spectrum shown (Figure 1) was obtained.¹ Further work led to spectra of lysozyme and bovine serum albumin.²

Figure 1 First NMR spectrum of a protein—ribonuclease at 40 MHz

Figure 2 First NMR spectrum of a polymer in solution—polystyrene

What did we learn about proteins from this spectrum? The most important thing was that one could obtain a spectrum where aliphatic, aromatic, and NH (as they were exchanged out) were roughly at the chemical shifts expected from those found in smaller compounds and that their peaks were fairly sharp. From diffusion and viscosity data, Kirkwood could estimate the correlation time for rotation of the protein molecules. We concluded that, if the molecules rotated as rigid bodies, there would be much more broadening from dipole–dipole interaction than we saw in the spectrum. The relative sharpness of the peaks seemed to imply that there was internal motion. This conclusion stimulated us to look at the spectrum of polystyrene (mol. wt. 1 500 000) in CCl₄ (Figure 2). Seeing lines about 20 Hz in width confirmed our idea that flexibility leading to local motion could result in sharp lines even in very large molecules. I believe that this is the first spectrum of a high polymer in solution to be published.

The only other work involving proteins which Arnold and I did was on exchange of protons with D₂O. We could see that the exchange rates of various groups spanned a wide range and noted (as others had before us) that the exchange rates were a function of pH value.³ We did not imagine how it might be possible to improve the resolution so that individual protons could be seen and then to be able to assign these lines. We could not foresee that NMR observations would eventually lead to detailed three-dimensional structural information about the proteins.

Schaefer, Jacob: A Brief History of the Combination of Cross Polarization and Magic Angle Spinning

Jacob Schaefer

Washington University, St. Louis, MO, USA

BACKGROUND

My focus in the Monsanto Company in the late 1960s and early 1970s was the development of Fourier transform techniques for the ^{13}C NMR analysis of polymers. After a seminar in the Chemistry Department of Washington University in 1971, I was complaining to Sam Weissman that most of the polymers I was trying to characterize were only partially soluble and that the resolution of spectra of swollen, cross-linked, multiphased systems was inevitably poor. Sam suggested forgetting about solvents and using magic angle spinning on the solid polymers instead. I objected that I didn't want to get involved in an experiment which was both difficult and dangerous. (I recalled a magic angle spinning talk featuring a slide showing the operator at a console separated from the magnet gap by a wall of sandbags!) Sam led me into his office, reached up to a book shelf, and took down a cigar box from behind a pile of journals. Within a few minutes he had assembled a magic angle spinning device consisting of a solid Lowe rotor suspended on two L-shape bronze wires. The short ends of the wires fitted into tiny holes machined into the center of each end of the rotor. The long ends of the wires were held by spacers and Teflon tape to the sides of a glass pipette. The tip of the pipette was aimed at flutes which had been cut around the barrel of the rotor. Sam gave a gentle puff and the rotor whistled into action: magic angle spinning and no sandbags.

Naturally, I was an immediate convert to spinning. I worked with Sam and his graduate student, Stanley Chin, to try ^{13}C NMR experiments on a chunk of truck tire. The tire was fashioned into a rotor by Jim Boyles, the same machinist in the Washington University Physics Department who had made rotors initially for Irving Lowe, and later for Richard Norberg and his students. The pipette was fitted into a cylindrical plastic holder which was the same diameter as a standard 13-mm sample tube, so no changes had to be made to the probe. The holder also had guides for the short ends of the L-shaped wires and these guides fixed the orientation of the spinning axis. The magic angle was set by rotating the entire plastic holder, which altered the spinning axis relative to the static field of the 2.1 T electromagnet. Stanley Chin had taped a cardboard protractor to the top of the plastic holder so that we knew approximately where the magic angle was. We determined how fast we were spinning by the sound. This primitive apparatus worked on the first try. The natural-abundance ^{13}C linewidths of the rubber

Figure 1 22.6-MHz Fourier transform ^{13}C NMR spectra of the aliphatic region of a carbon-black filled, vulcanized polyisoprene (a) static and (b) spinning at the magic angle at 1 kHz. The nonspinning spectrum of pure polyisoprene is shown in (c). (From Ref. 1)

in the truck tire were narrowed by about a factor of two by the spinning (Figure 1).¹

THE 1972 ASILOMAR EXPERIMENTAL NMR CONFERENCE

I presented these results at the 1972 Experimental NMR Conference, which was the first to be held at the Asilomar conference site on the Monterey peninsula. For most attendees the highlight of the meeting was the dramatic Wednesday evening talk given by Alex Pines, then a graduate student with John Waugh at MIT. Pines showed how natural abundance ^{13}C NMR spectra of crystalline solids could be obtained with high sensitivity using cross polarization transfers from protons. This was the first I had heard of cross polarization for ^{13}C and I was astounded by Pines's spectra: one beautiful slide

after the other made unambiguous correlations of structure, chemical shifts, and dynamics. This presentation convinced me immediately that cross polarization for sensitivity and resonant decoupling of protons for resolution would be important for the ^{13}C NMR of solid polymers. I do not recall thinking at this meeting of trying to combine cross polarization with magic angle spinning.

STEJSKAL'S FIRST ROTORS

Over the next few months I began reading the papers by Hartmann and Hahn, and Slichter and Ailion, to try to gain some insight into the physics of the cross polarization experiment. I was also continuing with magic angle spinning experiments, now in collaboration with Edward O. Stejskal who had joined my research group in the Physical Sciences Center of Monsanto. We became involved with an effort to characterize gases adsorbed on catalytically active molecular sieves, a project motivated by Monsanto's commercial interest in removing pollutants from auto exhaust. The sieves were powders and spinning experiments required a hollow rotor with a payload of about 0.5 cm^3 . Jim Boyles was retiring from active service at Washington University, so Ed Stejskal made drawings for a Lowe rotor incorporating Boyles's design features, and we asked a senior Monsanto machinist to give it a

Figure 3 Hollow Lowe rotor used in the mordenite spinning experiment of Figure 2. (From Ref. 2)

try. None of the first few attempts even came close to spinning smoothly. I was becoming worried that while spinning wasn't dangerous, maybe it was a bit too magical for comfort.

Stejskal volunteered to make the rotors. Ed had harbored a life long ambition to be a machinist and I believe he saw this as a golden opportunity. We bought a small, precision lathe and Ed attached several 'plastics and nonferrous metals only' signs (in a suitably official-looking font) to avoid conflicts with the professional machinists in the building. Ed's careful attention to detail, his understanding of what was demanded by the NMR experiment, and his flair for innovation at the lathe made a winning combination. He tried scores of design modifications until he had a rotor that spun easily and reliably. Even though we completely misinterpreted the results of our first experiments on adsorbed gases,² the spectra themselves were fine (Figure 2). Moreover, by the end of 1973 we had a sealable, hollow rotor for spinning experiments (Figure 3).

Figure 2 22.6-MHz Fourier transform ^{13}C NMR spectra of $^{13}\text{CO}_2$ adsorbed on a mordenite molecular sieve spinning at the magic angle at speeds between 50 and 3300 Hz. (From Ref. 2)

COMBINATION SPINNING EXPERIMENTS

The more I read about cross polarization the more I became convinced that magic angle spinning and cross polarization could not be combined. The latter required static dipolar coupling and the former removed it. A discussion with the most knowledgeable practitioners of cross polarization at the Dallas ACS meeting in April 1973 had reinforced this perspective. In particular, I was afraid that contributions from nonprotonated carbons with only weak couplings would simply disappear from the spectrum, and that the other carbon lines would have distorted, nonrepresentative intensities. Nevertheless, I felt that a *nonspinning*, cross polarization spectrum and the associated cross polarization transfer rates might be useful for characterizing molecular dynamics. In addition, I already knew that many of the glassy polymers that we intended to examine had short carbon spin-lattice relaxation times. Thus, I felt that fully relaxed, Fourier transform ^{13}C NMR of polymers would be practical and

informative because the resolution could be dramatically improved by relatively low-speed magic angle spinning to remove broadening due to chemical shift anisotropy, together with strong resonant decoupling of all carbon–proton interactions. Basically, I hoped to get dipolar-decoupled spectra of spinning glassy polymers like those of the rubbery polymers of Figure 1, and then use the resolution to measure T_1 and $T_{1\rho}$ values.

Thus, at the beginning of 1974, Stejskal and I continued to work both on cross polarization and on magic angle spinning, but with no specific intention of combining them. Ed had turned rotor production into a cottage industry. Because we were interested in a variety of engineering plastics, Ed made the rotors directly into analytical samples from melt-pressed molded bars and cylinders. The first rotors were all from Monsanto plastics: polystyrene, polyacrylonitrile, polystyrene/polyacrylonitrile copolymers, and poly(vinyl chloride). A typical result for polystyrene is shown in Figure 4. We were encouraged with the resolution that (almost) allowed our seeing three types of carbons. At the same time, we were collecting nonspinning, cross polarization ^{13}C NMR spectra of a variety of glassy polymers, including poly(methyl methacrylate) (Figure 5). I presented the results of both kinds of experiments at a Chemical Society of London meeting at Bedford, England, in July 1974. I carefully explained the motivation for both experiments and concluded, ‘As a practical matter, however, with lines narrowed by magic angle spinning, it may be difficult to establish the Hartmann–Hahn condition and so obtain the sensitivity enhancement of cross polarization’.³ Because of this outlook, and the preciousness with which we regarded the first few successful plastic rotors, we made no serious attempt at cross polarization combined with magic angle spinning for almost another year.

Actually, the ‘practical matter’ (see quote above) that really prevented even a casual attempt at cross polarization with magic angle spinning was the limitation of our pulse programmer. We were using crystal-controlled gate and delay

Figure 4 22.6-MHz Fourier transform ^{13}C NMR spectra of a polystyrene Lowe rotor spinning at 2 kHz at the magic angle with no decoupling of the protons (bottom) and with 30 kHz dipolar decoupling (top). The middle spectrum was taken with decoupling but no magic angle spinning. These spectra were obtained on June 27, 1974. (From Ref. 3)

Figure 5 22.6-MHz cross polarization ^{13}C NMR spectra of nonspinning poly(methyl methacrylate) as a function of the Hartmann–Hahn contact time. (From Ref. 3)

generators to make pulses on both carbon and proton rf channels. These units were linked by BNC cabling. The logic of the pulse sequence meant that the cabling had to be physically rearranged depending on whether we were going to do a Fourier transform or a cross polarization experiment. In addition, because the Lowe rotors had lifetimes of only a day or so (the bearing holes wore irregularly on stops and starts), we adopted the practice of not spinning a rotor until the pulse sequence and acquisition were clearly working. Thus, cross polarization and spinning were kept in separate compartments, both in our minds and in the laboratory.

THE FIRST CP MAS EXPERIMENTS

By May 1975 we had acquired additional gate and delay generators so that the logic for both Fourier transform and cross polarization pulse sequences was wired up and switch-selected. Thus, it was inevitable that the combination of cross polarization and magic angle spinning would be tried, and our first CP MAS ^{13}C NMR spectrum of a solid is shown in Figure 6 (middle). We clearly had a strong signal from the low-field, nonprotonated carbonyl carbon of poly(methyl methacrylate). Stejskal and I were astonished. Within 10 days we had finessed the operating conditions so that we knew that the nonprotonated quaternary carbon was also reporting (Figure 6, bottom). The methylene carbon was missing (and we didn't find it until we were able to increase the decoupling to more than 40 kHz about a month later), but otherwise the relative intensities looked representative of the numbers of carbons in the repeat unit.

I excitedly told my superior at Monsanto, Rolf Buchdahl, that Stejskal and I had invented a new analytical technique for polymers. The official name of our group at Monsanto was ‘New Analytical Techniques’. Rolf was not amused. Buchdahl suggested that I try the experiment on polycarbonate and I hurried off to look up the exact structure of the polycarbonate repeat unit. I quickly came back to Rolf and complained that there were too many aromatic carbons in polycarbonate that were almost but not quite alike, and that I couldn't promise that the new experiment would work. (As a precaution, I had decided to downscale my description of what we were doing from ‘new analytical technique’ to ‘new experiment’.)

Figure 6 22.6-MHz cross polarization ^{13}C NMR spectra of poly(methyl methacrylate) static (top) and with 3 kHz spinning at the magic angle (middle). These spectra were obtained on June 2, 1975. The proton radiofrequency field amplitude was 28 kHz, both for the 1 ms matched spin lock transfer to carbons and for decoupling. The bottom spectrum, which is displayed using a slightly wider frequency scale, was obtained with 35 kHz decoupling on June 12, 1975

Rolf assured me that the new whatever wouldn't be worth much if it didn't work on polycarbonate. To my relief, the CP MAS spectrum of polycarbonate was well resolved, and even better, carbon spin lock measurements indicated faster $T_{1\rho}$ relaxation for the protonated carbons than for the nonprotonated carbons (Figure 7). We immediately began issuing serious proclamations of the possibility of connecting the microscopic dynamics of polycarbonate with mechanical properties in June 1975, a practice that I have continued on a regular basis to the present.

PUTTING SPIN ON A BILLIARD BALL

Stejskal and I were excitedly trying CP MAS on every polymer we could get our hands on. We tried spinning protein powders in the hollow rotor but had difficulties getting the packing well balanced. We decided to machine a solid rotor out of a piece of bone just as Ed was doing with the plastic samples. At that time, it was legal to buy ivory billiard balls, so I called the A. E. Schmidt Company, a St. Louis supplier of billiards equipment with which my family had dealt for many years. They indeed had ivory balls in stock but they were

only rough-cut. This meant that the balls were approximately spherical but had to be trued before they could be used. I explained that I didn't care if they were only rough-cut because I didn't care whether the ball rolled straight or not. Silence on the phone. An ivory billiard ball showed up three days later perfectly trued and polished, and with an elaborate set of instructions on how to break it in before high-impact use. We ignored the instructions and instead used a jeweler's saw under water to cut a center section from the ball. This allowed Stejskal to machine a solid Lowe rotor whose spinning axis was along the eye of the tusk from which the ball had been turned.

CLOSE ENCOUNTERS WITH REVIEWERS

By the fall of 1975 we had generated a sizeable collection of CP MAS spectra of engineering polymers, various woods (including ebony), and the protein in ivory. We submitted a brief communication to the *Journal of the American Chemical Society* describing these results. The manuscript was not accepted based on the negative comments of one of the referees who wrote, 'Basically, there should not be polarization transfer due to a dipolar interaction between nuclei in a sample being spun rapidly at the magic angle.' Stejskal and I were a little at a loss as how to respond to this comment since we both agreed with it completely. We certainly didn't understand how the polarization was being transferred, but there was no doubt that transfers occurred, and to protonated and nonprotonated carbons alike. We knew that the transfers did not depend on some inherent flaw in the experimental set-up (the referee had suggested an error in the setting of the magic angle) because the transfers were just as efficient when the lines were broad as when they were narrow (Figure 6). Reluctantly, I added a paragraph of spin-mumbo to the manuscript, which, on reading today I am sorry to report, has not aged well. Nevertheless, the manuscript was accepted⁴ and the spectra that appeared in 1976 are not bad (Figure 8) even by present-day standards.

THE HAND DIAGRAM

Adamantane was one of our favorite samples for cross polarization because it was possible to observe two ^{13}C lines even with modest dipolar decoupling. In January 1976, we decided to see how much additional narrowing could be achieved with combined decoupling and spinning. Following the standard protocol, I established that the cross polarization sequence and the receiver section of the spectrometer were working properly before turning on the spinner. The spinner was gaining speed as the pulsing was going on. I noticed sizeable variations in the shot-to-shot signal-to-noise ratio on the oscilloscope and immediately stopped increasing the flow of the rotor drive gas. The rotor was now spinning at about 1 kHz and I was getting only about 20% of the expected signal intensity, but I couldn't find anything wrong with the spectrometer. I decided that trouble shooting would take considerably longer and that I had better give up on the experiment and turn off the drive gas. As the spinning speed decreased, the lost signal intensity suddenly returned. I stopped changing the gas flow and observed almost full

Figure 7 22.6-MHz cross polarization magic angle spinning ^{13}C NMR spectra of polycarbonate as a function of the time held in a 28 kHz spin-lock carbon rf field (with no proton rf field) prior to detection with 35 kHz proton decoupling. The ^1H - ^{13}C cross polarization transfer has discriminated against the protonated carbons. These spectra were obtained on June 12, 1975

Figure 8 22.6-MHz cross polarization ^{13}C NMR spectra of various solids without spinning (top) and with 3 kHz spinning at the magic angle (middle). Comparative solution state Fourier transform spectra are shown at the bottom of the figure. (From Ref. 4)

Figure 9 The amplitude of the proton-enhanced ^{13}C NMR signal in adamantane as a function of the Hartmann-Hahn mismatch with 2.2 kHz magic angle spinning (top) and without spinning (bottom). The arrows indicate where the cross polarization time constant was determined by measuring carbon signal intensity as a function of contact time. (From Ref. 5)

intensity. Another 10 minutes or so of this and I convinced myself that I was in control of the signal level. After 10 more minutes, I had convinced Stejskal.

For the next several hours, we made systematic variations in spinning speed and radiofrequency amplitudes resulting in the plot shown in Figure 9. Ed was determining cross polarization transfer rates using graph paper and a hand calculator. He used his 'on-line' plot to suggest new spectrometer settings for me. I recorded the resulting spectra and measured peak heights with a ruler to produce inputs for Ed's plots. We were afraid to stop the experiment because at the time the rotor that was spinning in the magnet was our only functioning hollow rotor, and damage was most likely to occur on stops. Ed ignored increasingly frantic calls from home that dinner guests had arrived long ago. After a while Ed said that the diagram looked like a hand. The hand grew a few more fingers, but we never changed the name. (A less-resolved plot we generated later for another system we referred to as a 'knuckle diagram'. This illustrates how catchy new NMR terms are born.)

WAUGH'S EXPLANATION

I was in the habit of calling John Waugh (he was always in his office around noon, Boston time) and pestering him for help with the mysteries of solids NMR. I told him of our strange CP MAS results on adamantane. Waugh was intrigued and offered to look at the data. A few days later he produced the basic explanation. As with all good theories, his explanation was simple and direct: cross polarization transfers work with no

Figure 10 The ^{13}C – ^{15}N cross polarization time constant as a function of the Hartmann-Hahn mismatch for L-[4- ^{13}C , amide- ^{15}N]asparagine spinning at the magic angle at 3205 Hz. (From Ref. 6)

complications when the spinning speed is slow compared to the homogeneous proton-proton interactions.⁵ This was certainly the case for the polymers and proteins we had examined, but it was not quite true for adamantane which has relatively weak proton-proton interactions. Thus, magic angle spinning does indeed interfere with cross polarization transfers *if* the sample is spun fast relative to *all* dipolar interactions. What I had been forgetting for the last two years was the obvious, well-known fact that 3 kHz spinning had virtually no narrowing effect on a 20 kHz proton linewidth. For adamantane, the 'hand diagram' arose from a combination of frequency and amplitude modulation of homogeneous dipolar coupling, and amplitude modulation of heterogeneous dipolar coupling, all produced by the spinning.⁵ For systems with only heterogeneous dipolar interactions,⁶ only amplitude modulations are present, and the hand loses a few fingers (Figure 10). In either case, strategies can be worked out so that weak couplings in the presence of fast spinning can still be used for transfers.⁶ In other words, magic angle spinning complicates the cross polarization process but doesn't short circuit it.

RETROSPECTIVE

I believe that the combination of cross polarization and magic angle spinning would have been discovered in the late 1970s in the absence of the events described above, or, for that matter, in the absence of Schaefer and Stejskal. However, for us, the experiment was a natural result of our efforts to solve polymer structure problems. It is possible, therefore, that our immediate application of CP MAS to complicated polymer systems helped to convince others of the utility of the technique and thus contributed to its early acceptance and subsequent popularity.

Schaefer, Ted: A Canadian Prairie Youth Discovers the Delights of NMR

Ted Schaefer

University of Manitoba, Winnipeg, Manitoba, Canada

On September 30, 1955, a Canadian youth aged 22 arrived in Oxford, UK, to become a research student of R. E. Richards. (Rex Richards had been a student of H. W. Thompson, a pioneer of infrared spectroscopy. The latter, a student of C. N. Hinshelwood and F. Haber, had once lodged in the home of Max Planck in Berlin.) That youth, myself, hardly appreciated the lucky concatenation of circumstances leading to his presence in the ancient city. I was born in a depression-ridden pioneer village which lacked most physical amenities, even roads. Nevertheless, a good basic education was available, furthered by my multilingual teaching father, and was followed by a sound training in the classical aspects of chemistry at the University of Manitoba; the post-World War II prosperity made university attendance possible although it was still a privilege. Science was glamorous in 1950. Had not the physicists proclaimed that a few grams of nuclear fuel could drive the Queen Elizabeth across the Atlantic?

Another link in the catenary leading to Oxford was the friendship between A. N. Campbell, my supervisor of an M.Sc. thesis on the phase diagram of lead–indium–tin, with W. G. Schneider at the National Research Council in Ottawa. I spent a summer in Bill Schneider's laboratory. Late that summer of 1955 a Varian HR-40 NMR spectrometer arrived. I watched entranced as Bill and H. J. Bernstein 'chased a ^1H NMR signal across the oscilloscope screen'—there was no magnetic flux stabilizer, not to speak of a field/frequency 'locking' device. Their signal-chasing culminated in the first comprehensive monograph on chemical NMR (1959), written with J. A. Pople.

The final circumstance was that Bill Schneider facilitated my acceptance by Rex Richards. My first night in Oxford was spent in a bare college room; I read myself to sleep with 'Three Men in a Boat'. Soon, however, I was deep in D. Bohm's book on quantum theory and similar texts. There was a great deal to learn. Unlike today, when a plethora of texts bewilders the novice, there were no NMR texts in 1955. One puzzled over the journals or sought advice. Even C. A. Coulson consented to answer mundane questions about perturbational calculations.

Rex Richards had a homebuilt 12.2-MHz spectrometer whose magnet was energized by lead–acid batteries. He suggested the measurement of the ^1H NMR spectra of NH_4NO_3 down to a temperature of 20 K. I carried the required liquid hydrogen from the Clarendon Physics Laboratory over to the Physical Chemistry Laboratory—musing about the neat fact that *para* hydrogen yields no NMR signal—and poured it into the precooled (liquid oxygen!) Dewar containing the NMR probe. The acquisition of the first derivatives of the NMR absorption signals entailed wearisome manipulations.

Rex did not tell me that this instrument had yielded spectra proving the existence of the hydronium ion.¹ This I learned from Ray Freeman, well into his doctoral work on gallium and cobalt NMR; the latter led to an influential paper² on

the paramagnetic contribution to the chemical shift. Another presence was D. F. Evans, later to do the first relative signs of coupling constants by double resonance.³ One took the abundant mental stimulation for granted.

In the end I determined some 1200 second moments (Van Vleck) of a variety of ammonium salts. Because the necessary integrations were done with hand-turned mechanical calculators, it helped to memorize the squares and cubes of many integers. The lineshapes and second moments displayed some curious behavior, indicative of subtleties in the motional characteristics of the ammonium ions (in an attempt to understand at least some of the details, I studied the pioneering work by Gutowsky, Pake, and Bersohn⁴). Indeed, such salts have provided challenges to numerous investigators over the years. Our eventual survey paper (less publishing pressure then) is still referenced on occasion, certainly as late as 1993. It is satisfying to have one's work noticed, of course, even when the surname is subjected to amazing spellings.

Rex Richards was also building a simple, high-resolution instrument⁵ based on a permanent magnet. He encouraged me to construct the radiofrequency bridge, the NMR probe, and a linear time base for field sweeping. My attempts began with sheets of shiny metal, progressed via bloody fingers and many revisions, ending with workable black boxes. One day, Rex conjured up M. Golay. The 30-MHz spectrometer was thereby endowed with an early set of printed circuits of electrical shims for the adjustment of magnetic field inhomogeneities. Golay also left me with the firm belief that spherical harmonics express the spatial distribution of almost anything and that a baby's rattle can be a scientific device. My eleventh attempt at a probe using everyday materials—yes, a cork will spin—was successful. On a Good Friday we had repeatable ^1H NMR spectra with peak widths of about 0.5 Hz for an undegassed sample. Today, careful shimming and digital enhancement will resolve half a dozen peaks in such an envelope, but in 1957 I felt proud of the \$10 probe. Furthermore, Rex's machine could be returned from ^1H to ^{19}F NMR in a few minutes, a time matched only later on commercial units.

It was a delight to see the many spectral patterns arising from different organic materials. Papers on such patterns appeared between 1955 and 1960, written by pioneers such as H. S. Gutowsky, C. P. Slichter, W. A. Anderson, H. M. McConnell, E. L. Hahn, J. A. Pople, among others. My own small contribution was to puzzle out the appearance of a spectrum from three nuclei, unequally spin–spin coupled to each other but with accidentally equal chemical shifts for two of the nuclei. My 1958 thesis called this an AA'B situation, the first use of the prime notation, later to be used more sensibly by other authors in distinguishing between 'chemical' and 'magnetic' equivalence.

Rex's machine could resolve some long-range coupling interactions, over as many as six formal bonds between the nuclei, as in 4-fluorotoluene. They have tantalized me ever since. In the hands of many experimentalists and theoreticians such interactions turned out to be exquisitely sensitive to the stereochemistry and internal flexibility of a molecule. Sometimes small internal rotational potentials followed for certain molecules in solution, occasionally in cases where other methods appeared to fail.

These facts are twigs on the branches of the elaborate tree into which NMR has grown in 50 years. Yet the satisfaction at having contributed to even one twig is such that I am deeply

grateful to fortune and to my numerous mentors and students for the chance to play in the glorious game called NMR.

Schneider, William G.: Early Research on High-Resolution Proton Magnetic Resonance

William G. Schneider

The subject of nuclear magnetic resonance has expanded in a remarkable manner since the first experiments on bulk matter in 1945. Early high-resolution work on liquids indicated that magnetic nuclei could detect small changes in chemical environment and promised a number of important applications in various branches of chemistry and chemical physics. In the last few years this promise has been fulfilled and the rapid development of instrumentation has made nuclear magnetic resonance one of the most powerful tools for investigating chemical problems.

—From the preface to the book, 'High Resolution Nuclear Magnetic Resonance', by Pople, Schneider, and Bernstein, McGraw-Hill (1959).

From a 1993 perspective, 34 years after the publication of our book, it is clear our view then of the potential of NMR and its future applications was very much understated. The rapid development of NMR, which was in full swing in 1959, has continued unabated and there are now few scientific disciplines not affected by its impact. These new developments, as was the case before 1959, have been driven by continuing research to understand basic principles and new applications, as well as enormous advances in high-quality magnets, sophisticated instrumentation, and computerization. Before 1959 it was easily possible to know personally most of the active researchers in NMR. The scientific literature in the field was sparse and almost every experiment yielded exciting new results.

The opportunity to enter in on the ground floor of a major new scientific development is not given to many scientists. I consider myself very fortunate to have had such an opportunity although in hindsight I have to admit my entry followed a somewhat circuitous path.

In 1946 I was appointed to the research staff of the Chemistry Division of the National Research Council of Canada in Ottawa. My research was focused on intermolecular forces, intermolecular potentials, and phase transitions. The discovery of proton magnetic resonance in bulk matter in 1945 was an exciting event for any physical chemist. How was it accomplished and what might it lead to? Subsequent research by physicists at Harvard and Stanford Universities led to the discovery of chemical shifts, i.e. a displacement of the nuclear resonance due to different chemical environments of the nucleus being measured. Here was the first indication of an important link to chemistry.

In 1951 I attended one of the national meetings of the American Chemical Society at which I encountered Prof. George Kistiakowsky, Professor of Chemistry at Harvard, with whom I had worked in 1941 and 1942 as a postdoctoral fellow. George talked about his current research interests and specifically about NMR. Some time ago he had attended a colloquium in the Physics Department at Harvard given by Prof. Purcell on NMR. As he listened to explanations of

magnetic coupling, of linewidths and lineshapes, it suddenly occurred to him it might be possible to use these properties to investigate hindered internal rotation in crystals, e.g. ammonium salts, methyl groups, etc. He then set out to explore these ideas and mentioned he had some Ph.D. students in his laboratory doing experimental work, notably Herb Gutowsky and Charles Reilly. 'They are getting some very interesting results.' And, he added 'NMR looks like a promising field; you should get into it.'

If further convincing evidence was needed, that same year Arnold, Dharmatti, and Packard observed three separated proton resonance signals in ethanol with intensities in the ratio of 3:2:1 corresponding to the three chemically distinct hydrogen atoms in the molecule. Additionally, about this time, Gutowsky and co-workers reported on their observations of multiple lines due to J coupling in ^{19}F and ^{31}P resonances in a number of compounds containing these nuclei. There was now little doubt that NMR could have an important future in research in chemistry, and entering the field became a personal goal. However, I had previously applied for and been accepted to take a one-year sabbatical at Cambridge University in England in the Department of Theoretical Chemistry headed by Prof. Sir John Lennard-Jones. In the end the decision was made to delay a possible NMR initiative until after my return.

My sabbatical, from September 1952 to September 1953, was a stimulating experience and scientifically very profitable. Whilst at Cambridge I had many interesting discussions with Dr. John Pople, a very able young researcher who was obviously going to make his mark as a theoretical chemist, and who later was to become a collaborator in our NMR research activities.

On my return to Ottawa I started to review the experimental requirements and options for a research proposal in NMR. The key component for high-resolution work is the magnet which must have a very high degree of field homogeneity over the volume of the sample, as well as a high degree of stability. It soon became apparent that cost would be a major stumbling block, and that such a large investment for my small research group was not likely to be approved. To minimize this risk it was decided to bring on board as a collaborator Dr. Harold Bernstein, head of a small research group in infrared and Raman spectroscopy. Harold had expressed an interest in NMR as a potential new research tool.

By this time we were aware that Varian Associates, a company in Palo Alto, CA, were in the process of developing large electromagnets suitable for high-resolution NMR. The company had also recently taken on staff a very able young physical chemist, Dr. James Shoolery, who together with the company engineers had developed complete instrumentation for high-resolution NMR. The rf signal detection system was of the double-coil type, i.e. with separate and orthogonal transmitter and receiver coils surrounding the sample. The prototype instrument operated at 30 MHz at a field of 0.7059 T for proton resonances. A visit to the company proved to be a rewarding experience. By this time a 40 MHz instrument was being developed with an electromagnet having 12-in. pole faces and fields up to 1.4 T. Jim Shoolery demonstrated the performance of the instrument, which was indeed impressive. The Varian visit quickly resolved for us the 'make or buy' option with respect to equipment acquisition. In fact, Varian's achievement in being able to market a complete NMR spectrometer so early in a new research field was

indeed remarkable. Very fortunately our research proposal was approved by the NRC authorities.

Within our own laboratories, at the time already crowded, there was no suitable area with the necessary reinforced floor to accommodate the weight of the magnet. Eventually the Director of the Chemistry Division, Dr. E. W. R. Steacie, offered us one of his laboratory units. It had been equipped for research in radiation chemistry using a highly radioactive cobalt cell as a source. This had been installed inside a concrete enclosure with walls and ceiling two feet thick to provide necessary shielding, and occupied most of the floor space of the laboratory. It had a fairly wide and heavy sliding door and several observation ports, as well as a solid foundation. 'Could this laboratory satisfy your requirements?' Since no immediate alternatives seemed to be available, we accepted the challenge and the 'concrete hut' became the home for the new NMR spectrometer.

Our early research efforts were directed toward understanding and developing basic principles of proton resonance spectroscopy as a tool for research in chemistry. The most important magnetic parameters measured were chemical shifts, proton spin-spin coupling constants, and proton spin relaxation times. These must then be systematically interpreted so as to yield information useful to the chemist. In order to build up a base of knowledge for this purpose, the proton magnetic resonance spectra of a variety of classes of organic and inorganic compounds of known structure were recorded and analyzed.

After our experimental program was well underway, I had invited John Pople to the National Research Council as a visiting scientist. Having accepted, he was able to arrange extended leaves from Cambridge University during the course of several summers as well as periodic shorter visits in between. John made important contributions to the NMR research program, and our collaboration was both stimulating and productive.

An essential part of high-resolution proton resonances of more complex molecules is that of spectral analysis. When the chemical shifts of nonequivalent protons in the molecule are well separated it is usually a simple matter to assign individual resonances in the spectrum, especially when spin-spin interaction multiplets are also resolved. However when the chemical shift separation (in frequency units) is of the order of magnitude of the proton-proton spin coupling constants, the NMR spectrum consists of a complex pattern of lines and the regularity of individual multiplets is no longer discernible. To interpret a spectrum of this kind requires a quantum mechanical analysis of the energies and relative intensities of transitions among the spin states of the interacting protons in the molecule. A system of nomenclature was devised which distinguishes protons with large chemical shifts from those with small chemical shifts in the same molecule. Starting with two proton systems and building up to larger multiproton systems, it was possible to develop a systematic procedure for spectral analysis.

Another important research focus related to understanding and interpreting the particular atomic and molecular properties which contribute to observed chemical shifts of proton magnetic resonances. It soon developed that this involved both *intramolecular* and *intermolecular* contributions. The major contribution to the chemical shift arises from the induced diamagnetic shielding by electrons surrounding the proton

and the nucleus to which it is bonded. The electronegativity of the latter also has a major effect and could be observed in molecules where the proton is several bonds removed. Another important intramolecular contribution, first interpreted by John Pople, is the so-called 'ring current' effect in aromatic molecules. In a magnetic field the delocalized π electrons give rise to a ring current resulting in a magnetic moment perpendicular to the plane of the ring which interacts with the proton spin. The magnitude of this contribution depends on the position of the bonded proton from the center of the ring (and adjacent rings), and the angle of its position with respect to the plane of the ring. Detailed analyses of the spectra of benzene and multiring aromatic hydrocarbons, as well as substituted benzenes containing protons in the substituents, gave satisfactory agreement with the calculated contributions from the ring current effect.

A small intramolecular contribution to the chemical shift of great interest to organic chemists relates to molecular conformation and configuration. Differential contributions to the chemical shift of protons in different molecular isomers are observable unless the thermal interconversion of isomers is sufficiently rapid at the temperature at which observations are made to average out this differential. This can occur where hindered internal rotation becomes possible, as, for example, in substituted cyclohexanes able to interconvert from *chair* to *boat* conformations. Separated chemical shifts for *axial* and *equatorial* protons in carbohydrate molecules provide unique data for establishing their conformations. Isomeric differential proton chemical shifts are due to rather subtle small differences in electron configuration of individual isomers which are not well understood.

In another class of organic compounds, namely, conjugated aromatic molecules, the π -electron densities at individual carbon atoms can be calculated on the basis of molecular orbital theories. By measuring proton chemical shifts (and in some cases ^{13}C chemical shifts) in aromatic compounds and aromatic ions, it was found that to a first approximation the measured shifts correlated well with the calculated electron densities of the carbon atom to which the proton is bonded.¹

Turning now to *intermolecular* effects, early proton resonance measurements of compounds in solution exhibited some pronounced solvent effects. This was at first a surprising result, since for some solutes the shifts involved were quite large. A systematic study was undertaken to identify and interpret the shifts arising from intermolecular interactions. This included proton resonance measurements of the test compound in the gaseous state at low pressure (where intermolecular effects should be virtually absent) and in various solvents over a wide range of dilution. It was found that the largest shifts occur when the proton being measured is capable of forming hydrogen bonds, either with its own molecules or with solvent molecules. Another fairly large contribution arises when the proton is bonded to a molecule capable of interacting strongly with π electrons in an aromatic solvent, such as benzene, which tends to orient the H-C bond of the solute perpendicular to the aromatic ring. The above-mentioned ring current effect then gives rise to a pronounced resonance shift. Other contributions observed include those arising from the bulk diamagnetic susceptibility of the solvent, its magnetic anisotropy, polar effects of the solvent, and van der Waals interactions with the solvent.²

Time-dependent proton resonance measurements provide a powerful tool for studying a variety of chemical processes, a number of which were explored. These include, for example, proton-exchange processes, hindered internal rotation about single bonds, and tautomerism. Since these are thermally activated processes, measurements are required over an appropriate range of temperatures and can yield the respective rate constants and thermal activation energy.

In 1956, we decided to host a research conference on high-resolution NMR at the National Research Council to which then active researchers in this field were invited. It was an outstanding success. The new research initiatives reported on were exciting and demonstrated how rapidly NMR research was expanding. Thereafter an NMR research conference became an annual event, each hosted by a different volunteer research group. Ultimately it spread beyond North America and became an annual international conference.

Meanwhile organic chemists were becoming aware of NMR as a powerful new tool for determining structures of complex molecules and frequently brought samples for proton resonance analyses. It was usually possible to confirm a specific structure or to eliminate proposed alternative structures.

After the Ottawa Conference, we came to the conclusion there was a real need for a book on high-resolution NMR which would cover the basic principles and applications to chemistry. We debated undertaking such a major project with considerable apprehension. None of us was prepared to sacrifice a great deal of time from our on-going research programs. In the end we agreed on a tripartite authorship and to share the workload. The enormity of the task we had taken on became clear after the first draft when an excessive amount of time and energy was needed to produce a coherent and condensed final text. By this time John Pople had accepted a post with the National Physical Laboratory in Teddington and his visits to Ottawa were necessarily less frequent. The book was finally published in 1959.

During the course of our early research activities quite a number of students and postdoctoral fellows were first introduced to NMR research in our laboratory and made many important contributions. It is a pleasure for me to acknowledge my great indebtedness to them. Most of them accepted positions in chemistry departments in universities where they continued their research and set up lecture courses to train the next generation of NMR scientists. With similar developments emanating from other early NMR research laboratories, it transpired that NMR research became institutionalized in a relatively short period of time and set the stage for its subsequent remarkable growth and achievement.

I would like to express my gratitude and appreciation to Dr. John Pople and to the late Dr. Harold Bernstein for their support during the years of our active collaboration.

Scott, A. Ian: ^{13}C NMR Studies of Biosynthesis. A Quarter Century in Retrospect

A. Ian Scott

Texas A&M University, College Station, TX, USA

We began our first experiments 25 years ago on the application of ^{13}C NMR to investigate the biosynthesis of vitamin B_{12} , one of Nature's most complex molecules produced by bacteria. First, in order to determine both the identity of the 'building blocks' and the sequence by which they are assembled in a 20-enzyme cascade in cells of *Propionibacterium shermanii*, we set about the synthesis of ^{13}C -enriched precursors none of which was available commercially. Our primitive NMR equipment was a 1960 vintage Bruker HFX 90 MHz (housed in A. Lipsky's laboratory in the Yale Medical School) which had been converted to FT (with an IBM 1800 computer) by Dr. Robert Cushley. It was by no means certain at the outset that the biosynthetic incorporation of our synthetic precursors into B_{12} using whole cells would give a sufficient signal-to-noise ratio above natural abundance at the sensitivity of the machine. However the appeal of noninvasive analysis overcame all of our misgivings. We were also encouraged by the 1966 experiment by Tanabe at Stanford who observed the ^1H satellites of enriched carbons after administering ^{13}C acetate in his classic work on griseofulvin biosynthesis.

After painstakingly isolating 40 mg of enriched B_{12} (about 100 times the amount needed with today's instruments) with C. A. Townsend, M. Kajiwarra, and K. Okada, we were able to demonstrate^{1,2} that, contrary to previous literature (in which ^{14}C was used as a tracer), seven of the eight methyl groups were derived from methionine and that, most importantly, these methyls were inserted into uro'gen III, the same template which is used for heme and chlorophyll biosynthesis. From that moment we became wedded to carbon-13 as a probe for intermediacy in metabolic pathways and for studying the biosynthetic enzymes with ^{13}C -enriched substrates and inhibitors.³ The latter work has now matured from the first experiments (with Paul Malthouse in the early 1980s) where we used cryoenzymology ($-25^\circ\text{C}/\text{DMSO}/\text{buffer}$) to detect covalent complexes of the intermediates in the hydrolysis of peptides catalyzed by serine and thiol proteases,⁴ to the more recent discovery (by ^{13}C NMR of labeled enzyme) of the unique dipyrromethane cofactor of the polymerizing enzyme of porphyrin and heme biosynthesis (PBG deaminase)⁵ which, in spite of an M_r value of 33 000, reveals only the enriched carbons and the protons attached to them, Figure 1.

The second event which told us that high-field FT NMR would be absolutely necessary for our future experiments came in 1977 when my postdoctoral colleague, Tony Irwin, working with L. Siegel at Duke University on the 670 000 molecular weight six-electron sulfite reductase enzyme from *E. coli*, was able to isolate from a total of 2 g of protein (containing 19 classical and two 'nonclassical' hemes), ca.

200 μg of the isobacteriochlorin, sirohydrochlorin, which is part of the electron transport machinery of the enzyme. The ^{13}C spectrum at natural abundance was obtained for us at Varian by Jim Shoolery at 20 MHz using the first generation of Varian FT-80 instruments. The acquisition of the spectrum from the necessary one million transients took 11 d continuous operation over the Christmas vacation.⁶ For the next decade we seldom had more than 50–100 μg of the various B_{12} intermediates, but having quickly adapted to the world of ^{13}C -enrichment ($\geq 90\%$) we have enjoyed the luxury of the illusion that we were working with 10 mg samples, as far as the signal-to-noise ratio was concerned.

Also in 1977, we began our first in vivo ^{13}C NMR experiments⁷ just as R. G. Shulman (then at Bell Laboratories) was starting to follow the fate of ^{13}C -glucose in living cells. An early experiment in Texas involved feeding 2 mg of ^{13}C -U-glucose to the most abundant insect we could find in the lab—the Texas cockroach (*Periplaneta americana*). In order to provide the necessary signal lock and to avoid drowning the specimen, we added D_2O carefully to the 10-mm tube up to the 'shoulders' of the cockroach, only to discover later (from our colleagues in entomology) that cockroaches breathe through their sides! Subsequent experiments with *Heliothis spp.* (tobacco budworm) were however much more successful (and rigorous) leading to the identification of several metabolites⁸ and to our later work with trypanosomes.⁹

It also seems remarkable to me that when we moved to Texas from Yale in 1977 there were no superconducting magnets in any of the Texas Universities, yet all of our subsequent work has depended on high-field NMR spectroscopy with biosynthetic enzymes and their enriched substrates and inhibitors. More recently (1987) we entered the world of genetic engineering,¹⁰ which has provided us not only with massive amounts of our favorite enzymes but indeed the opportunity to use on-line NMR spectroscopy to follow the mechanisms of more than 30 enzymes necessary to make B_{12} , penicillins, steroids, and antitumor alkaloids. To solve these problems it is now essential to have available in the same laboratory, organic synthesis with stable isotopic enrichment, molecular biology for cloning and overproducing the enzymes and, most importantly, 300–500 MHz NMR, 7 d a week, 24 h a day. We have come a long way from the first experiments of the late 1960s, but it is abundantly clear in retrospect that we could not have solved **any** of our biosynthetic and structural problems without dedicated NMR instrumentation which, to this day, is at the heart of all of our research on natural product biosynthesis, and on the enzymes which control the production of these biologically important molecules.

Figure 1 High-field NMR spectra of *E. coli* PBG deaminase (~1 mM) specifically ^{13}C -enriched in the dipyrromethane cofactor via $[5\text{-}^{13}\text{C}]\text{-ALA}$. (a) 125 MHz ^{13}C NMR difference spectrum between separate deaminase samples (pH 8) grown in the presence or absence of $[5\text{-}^{13}\text{C}]\text{-ALA}$ demonstrating the four ALA-derived ^{13}C -enriched carbons. (b) Difference spectrum of samples as in (a), recorded at pH 12. Upon alkaline denaturation, the resonance assigned to the thiomethyl carbon has shifted downfield to δ 29.7 ppm, in closer agreement to a model cysteine thiomethylpyrrole conjugate. (c) ^{13}C INADEQUATE spectrum (pH 12) of $[5\text{-}^{13}\text{C}]\text{-ALA}$ -derived deaminase demonstrating the coupling of adjacent carbons, confirming the head-to-tail dipyrromethane structure. (d) Isotope-edited 300 MHz ^1H NMR spectrum (pH 12) of biosynthetically enriched deaminase (2 mM) showing the three pairs of signals originating from only those protons directly bound to the ^{13}C carbons derived from $[5\text{-}^{13}\text{C}]\text{-ALA}$. The observed antiphase splittings are due to the one bond $^1\text{H}\text{-}^{13}\text{C}$ coupling. (e) Normal proton spectrum of same sample illustrating the degree of selection afforded by the pulse sequence for spectrum (d). Insert: structure of the dipyrromethane cofactor and summary of ^1H and ^{13}C chemical shifts and coupling constants obtained at pH 12.

Seelig, Joachim: NMR and Membrane Structure

Joachim Seelig

University of Basel, Basel, Switzerland

In the late 1960s cooperative transitions in biopolymers were a highly popular theme among biophysicists. The Watson–Crick double helix was firmly established, the genetic code was deciphered, and the first transfer-RNA single crystals were simultaneously obtained in five different laboratories. Biophysicists were particularly interested in the melting behavior of double-stranded DNA since the separation of the helical double strands into a random-coil single strand was the prerequisite for ribosomal translation. In parallel, peptide chemists like P. Doty, E. Blout, and H. A. Scheraga were investigating peptide structure and folding with a large variety of synthetic peptides, with particular emphasis on the helix–coil transition of these synthetic molecules. The elegant modification of the linear Ising model (originally developed for ferromagnetism) by Zimm and Bragg was highly successful in explaining the observed experimental data of helix–coil transitions for both nucleic acids and polypeptides.¹ Modern statistical mechanical textbooks which gave ample space to relevant biological problems, such as that of N. Davidson, contributed to a rapid acceptance of the Zimm–Bragg theory.

As far as biological membranes were concerned, the physical situation was less clear. On the one hand, it was discovered in 1965 that membranes are highly fluid structures. By tagging membrane proteins with a fluorescent probe, it could be demonstrated convincingly that membrane proteins were diffusing in the plane of the biological membrane with a diffusion constant of the order of $D \sim 10^{-9} - 10^{-10} \text{ cm}^2 \text{ s}^{-1}$, only a factor of 100 smaller than the diffusion of the same molecules in water. Harden McConnell and his co-workers using different types of nitroxide spin probes then demonstrated with EPR techniques that the physical basis for protein movement was a fluid lipid matrix. Lipids were also the only known biological molecules which exhibited polymorphic structures. Depending on the environment, they were organized in bilayer, hexagonal, cubic, or micellar phases, the overall geometries of which were characterized by V. Luzzati in Paris using X-ray diffraction. The Dutch chemist L. van Deenen developed new synthetic methods which made it possible to tailor lipids of well-defined fatty acid composition and D. Chapman showed with infrared and differential scanning calorimetry that lipids with two saturated fatty acyl chains were undergoing a highly cooperative gel-to-liquid crystal phase transition.

Over the period 1966–68, I was a graduate student with M. Eigen working together with G. Schwarz on the kinetics of the helix–coil transition of polypeptides. In the winter of 1967–68, D. Chapman reported his exciting results on the phase transition of lipid membranes obtained by differential scanning calorimetry at a symposium in the Bavarian Alps in honor of M. Eigen's Nobel Prize. Being already biased toward cooperative transitions as a result of my studies on the helix–coil equilibrium, I wondered if a similar approach could also be developed for lipid membranes. However, molecular

details were missing. Should membranes be considered as two-dimensional cooperative systems or was their behavior more comparable with three-dimensional crystals? It seemed to me that the only experimental method capable of providing solid experimental results was the nitroxide spin-label EPR method.

In September of 1968 I started my postdoctoral research with Harden McConnell. When I arrived, the first fatty acid spin labels had been synthesized by W. Hubbell and the first description of an anisotropic spin label motion had been formulated. Very soon I succeeded in recording oriented membrane spectra and I could also give a straightforward interpretation of the EPR spin-label spectra in terms of the order parameter formalism which I borrowed from the NMR theory of liquid crystals developed by A. Saupe.² Saupe had dissolved small molecules in liquid crystals and was the first to observe ^1H NMR high-resolution spectra of molecules with anisotropic motion. He also provided the full theoretical background for the analysis of high-resolution NMR spectra with anisotropic motion. Reading Saupe's papers, it struck me that liquid crystals had many features in common with biological membranes and that it should be possible to take advantage of the residual anisotropic dipolar splittings to elucidate their structure. However, due to the large number of protons attached to a single phospholipid molecule, ^1H NMR spectra of membranes gave rise to broad featureless spectra even when recorded with homogeneously aligned membrane systems. The molecular analysis of such spectra was hopeless. However, it was possible to prepare single-walled phospholipid vesicles of small diameter ($\sim 30 \text{ nm}$) by sonification which then yielded high-resolution NMR spectra of good quality, since dipolar interactions were averaged out due to rapid vesicle tumbling. A. F. Horwitz, M. Klein, S. Chan, and co-workers characterized the ^1H and ^{31}P NMR relaxation times of these vesicles, and J. Metcalfe was the first to record ^{13}C NMR spectra of such model membranes, the latter providing a much better molecular resolution.

After returning to Basel, Switzerland, in 1970, I first continued with spin label EPR work. However, in 1972, the Biocenter was inaugurated and money was provided for a 90 MHz FT NMR instrument. Since I had no personal experience with NMR, I discussed matters with P. Diehl who had been involved in the NMR of liquid crystals almost since its beginning. Diehl was also the first to publish a high-resolution deuterium NMR spectrum in 1956 and had laid the groundwork for all future deuterium NMR.³ Whilst discussing the various options for the new instrument, Diehl asked me if I had ever considered ^2H NMR since the ^2H nucleus had a quadrupole moment. It occurred to me that ^2H NMR should indeed have considerable advantages compared with spin-label EPR or ^1H NMR: the quadrupole splitting of the deuterium nucleus should provide information on the anisotropy of motion in much the same way as the hyperfine anisotropy of the spin-label group. At the same time, ^2H NMR would avoid the perturbing influence of the nitroxide radical since the van der Waals radii of ^1H and ^2H were rather similar.

Hence we set out in 1973 to synthesize selectively deuterated fatty acids and lipids, and in 1974 my wife and I could indeed publish a first quantitative description of a phospholipid bilayer using exclusively deuterium NMR.⁴ A further step in membrane analysis was then the use of ^{31}P NMR. G. Radda and co-workers had one of the first 270 MHz spectrometers and had reported rather unusual

lineshapes for the ^{31}P NMR spectra of membranes which were explained qualitatively by the phosphorus chemical shielding anisotropy. About the same time, M. Klein and S. Kohler at Berkeley and R. G. Griffin at MIT measured the principal components of the ^{31}P chemical shift tensor in crystalline phospholipid model compounds, allowing finally a complete quantitative description of the lipid phosphate moiety. Using this information, W. Niederberger and I then succeeded in measuring the first proton-decoupled ^{31}P NMR spectra of lipid membranes and we could provide a full quantitative description in terms of the order parameter formalism.⁵ When I talked to John Waugh (who was *the* authority on solid state NMR) about our proton-decoupled phosphorus NMR spectra, he was disbelieving at first since he thought that 20 W decoupling power would be much too low for membranes. However, when I showed him the experimental results he was convinced and remarked: 'Joe, you and I are the only ones who understand ... membranes!' Hence, by the end of 1976, the NMR toolbox for membrane studies was wide open and provided the instruments for many biophysical membrane studies to come.

Sergeyev, Nickolai M.: Isotope Effects On Spin–Spin Coupling Constants

Nickolai M. Sergeyev

Moscow State University, Moscow, Russia

In liquids, the energy of the nuclear spin–spin interaction is given by

$$E(\mu_1, \mu_2) = J_{12}h \mathbf{I}_1 \cdot \mathbf{I}_2 \quad (1)$$

where $\mathbf{I}_1$ and $\mathbf{I}_2$ are the dimensionless nuclear spin vectors and J_{12} is known as the spin–spin coupling constant. As the nuclear magnetic moments μ_1 and μ_2 are proportional to the magnetogyric ratios, γ_1 and γ_2 , it is obvious that the coupling constant J_{12} depends on the product $\gamma_1 \cdot \gamma_2$

In order to be independent of the magnetic properties of interacting nuclei, Pople and Santry¹ suggested using reduced coupling constants defined by

$$K_{12} = (4\pi^2/h\gamma_1 \cdot \gamma_2)J_{12} \quad (2)$$

where K_{12} depends only on the electronic (i.e. chemical) structure. The use of K_{12} allows one to replace one interacting magnetic isotope by another and thus to obtain spectral information which is often lost from the NMR spectrum due to the degeneracy of the spin system. Indeed, for a group of magnetically equivalent nuclei (such as, for example, protons in a methyl group), it is impossible to extract information about spin–spin coupling constants between protons. However, if a proton in a methyl group is replaced by an isotope (^2H or ^3H), the degeneracy is removed and the corresponding splittings become observable. The only question that remains is whether the chemical structure at such replacements changes or not.

The notion of such ‘structural effects’ was put forward for the first time by Gutowsky et al. in 1962.² They were interested in the measurement of geminal H, H spin–spin coupling constants in compounds of the type CH_2XY , but in many cases they met the problem of degeneracy in the ^1H NMR spectra. They suggested using compounds of the type CHDXY where one can measure H, D couplings and then use the ratio of magnetogyric ratios to transform to the H,H-scale by using the relationship

$$J^*(\text{D}, \text{H}) = (\gamma_{\text{H}}/\gamma_{\text{D}})J(\text{D}, \text{H}) \quad (3)$$

However the question of the ‘structural effects’ should now be taken into account. Gutowsky et al. suggested that the replacement of H by D may affect angle-bend averaging (as the mean H–C–H angle may be slightly larger than the corresponding angle in the H–C–D case). At that time the dependence of the geminal H,H coupling constants upon the interbond angle was the subject of lively discussion. It had been believed that the angular dependence of the geminal coupling constant in the CH_2 group was nonlinear. This meant

that the vibrations should result in a small difference in the values of $^2J(\text{H}, \text{H})$ and $^2J^*(\text{D}, \text{H})$. However, this needed experimental support. A test was impossible as the authors could not measure $J(\text{H}, \text{H})$. They made an attempt to check this idea by measuring the geminal $J(\text{F}, \text{H})$ and $J(\text{F}, \text{D})$ coupling constants in compounds of the type CFHXY and CFDXY . However the accuracy was not sufficient to obtain any noticeable difference, so no conclusion was reached. This was perhaps not so unfortunate, because at that time the sign of geminal coupling constants for the CH_2 group was erroneously believed to be positive, so any isotope effect would have been misinterpreted.

In 1962, Ebsworth and Turner³ studied deuterated silanes and, using the wiggle-beat method in ^1H NMR, obtained very accurate values for $J(\text{D}, \text{H})$ of 0.427 (± 0.003) Hz and 0.412 (± 0.004) Hz for SiH_3D and SiHD_3 , respectively. This was the very first observation of an isotope effect on coupling constants. It is worth noting that the accuracy obtained in 1962 has not been exceeded significantly during the last 30 years in spite of the revolutionary changes in NMR spectroscopy made by introducing the pulse Fourier transform technique. It is also worth noting that in both experiments with SiH_3D and SiHD_3 the authors measured $J(\text{D}, \text{H})$, so the problem of comparison with any H,H coupling constants in silanes remained unsolved.

Our group at the Department of Chemistry at Moscow University (A. A. Borisenko, Yu. A. Ustynyuk, and the author) encountered the problem of isotope effects on coupling constants at the beginning of the 1970s when we performed investigations on some phosphonates and phosphates containing P–H bonds,⁴ for example $(\text{C}_6\text{H}_5)_2\text{PH}$ and $\text{H}_2\text{P}(\text{O})\text{OH}$. To obtain greater concentrations of these compounds, deuterated methanol or heavy water were used as solvents. However, the ^{31}P NMR spectra of these compounds were more complicated than we had expected. For example, with $\text{H}_2\text{P}(\text{O})\text{OH}$ we observed the spectrum reproduced in Figure 1 where at least three groups of signals are seen: a 1:2:1 triplet, a doublet of 1:1:1 triplets, and a quintet of lines with relative intensities 1:2:3:2:1. This proved without doubt that the protons at phosphorus had been partially replaced by deuteriums during sample preparation and what we observed was indeed

Figure 1 The ^{31}P NMR spectrum at 40.5 MHz of partially deuterated hypophosphorous acid. The lines marked ‘a’ are the 1:2:1 triplet from H_2POOH , the doublet of 1:1:1 triplets is from HDPOOH (b), and the 1:2:3:2:1 quintet is from D_2POOH (c). Reproduced by permission of Molecular Physics

the spectrum of a mixture of isotopomers containing different numbers of deuteriums at phosphorus, i.e. $(\text{C}_6\text{H}_5)_2\text{PH}_2$ (triplet), $(\text{C}_6\text{H}_5)_2\text{PHD}$ (doublet of triplets), and $(\text{C}_6\text{H}_5)_2\text{PD}_2$ (quintet). The spectra of different isotopomers were shifted relative to each other revealing the isotope shift on ^{31}P nuclei due to D/H replacement. Even more interesting, however, was the fact that the $J(\text{P,H})$ and $J^*(\text{P,D})$ values in $(\text{C}_6\text{H}_5)_2\text{PHD}$ were 199.42 and 201.3 Hz, respectively, compared with $J(\text{P,H})$ in $(\text{C}_6\text{H}_5)_2\text{PH}_2$ which was 199.3 Hz. This allowed us to measure the primary and secondary isotope effects.

In general, we defined the primary effect for X,H coupling in a molecule of type Y–X–H as

$$\Delta J^{\text{P}} = (\gamma_{\text{H}}/\gamma_{\text{D}})J(\text{X,D}) - J(\text{X,H}) \quad (\text{in Y-X-H}) \quad (4)$$

and the secondary effect for X,H coupling in a molecule of type XH_2Y as

$$\Delta J^{\text{S}} = J(\text{X,H}) - J(\text{X,H}) \quad (\text{in XHDY}) \quad (5)$$

We found that for $^{31}\text{P,H}$ coupling constants the primary isotope effects were of the order of 2.0 Hz for three-coordinated phosphorus and about –5 Hz for four-coordinated phosphorus, while the secondary effects were about 0.12 and 0.58 Hz, respectively. As the $^{31}\text{P,H}$ couplings in P(IV) compounds are substantially larger than those in P(III) compounds, we concluded that the primary effects are of the order of 1% and the secondary isotope effects are about 0.1% for both types of phosphorus.

In the same year (1971), another paper was published dealing with isotope effects on $J(^{31}\text{P,H})$.⁵ Wojciech Stec from Poland working as a postdoc with Prof. Van Wazer at Vanderbilt University performed a study of the ^{31}P NMR spectra of dialkylphosphonates of the type $(\text{RO})_2\text{P}(\text{O})\text{H}$ (protonated and deuterated at the O–H bond) and found that the ratio $J(^{31}\text{P,H})/J(^{31}\text{P,D})$ was not invariant but changed from 6.50 to 6.52. Unaware of isotope effects on coupling constants, the authors suggested that the different ratios of coupling constants were due to solvent effects. They believed that phosphonates formed hydrogen bonds with methanol and that $\text{P-D}\cdots\text{O}$ bonds differed in energy from $\text{P-H}\cdots\text{O}$ bonds.

Both papers^{4,5} were published in November 1971, although the paper by Stec et al. was received by *J. Phys. Chem.* in March whilst our paper was received by *Mol. Phys.* in June. It is interesting to recall a puzzling episode when our paper was submitted.

It was first sent in February, but two months later it became clear that it was lost as the editor, Prof. Buckingham, had not received it. We sent a copy (actually, slightly modified) and after a month the editor informed us that he had unexpectedly received two versions of the same work. The problem for him was which manuscript to choose. He noticed that one of the envelopes had already been opened. He sent us this envelope to confirm that it was the first version. Meanwhile detailed study of the two manuscripts revealed to him which was the later one. In any case Prof. Buckingham kept only one manuscript for further consideration. Probably taking into account the special circumstances in which the manuscript had been received, he suggested not sending it again to Moscow and even proposed helping with checking the proofs. Indeed the paper was published fairly soon after.

The observations of isotope effects on coupling constants were first met with some skepticism, as they referred to systems which might be affected by solvent effects. Shortly after, McFarlane and Rycroft made a careful reinvestigation⁶ using several solvents including cyclohexane. Considering cyclohexane as a neutral solvent, they concluded that the situation was more complicated than the previous authors had believed^{4,5} because the observed isotope effect was a sum of both intrinsic and thermodynamic effects. However, in any case they confirmed the existence of isotope effects on coupling constants.

Another curious episode with our paper⁴ was connected with its translation into English. At that time publication of papers by Soviet authors in western scientific journals was not welcomed by the academic and government authorities in Moscow. In order to publish in the West one needed to obtain special permission from the KGB which had ‘otdel’ sections at any university and in any office with more than five employees. An anecdote from that time stated that among any five randomly chosen persons at least one would be from the KGB. Most of us defied the law and without obtaining permission submitted manuscripts often with the help of persons going abroad. Such tricks were possible as the system for controlling scientific publications was absurd. But it was still unpredictable and very dangerous. Sometimes you were not allowed to submit the paper abroad, sometimes you might be asked to publish the manuscript in Russian first, sometimes the manuscripts were lost.

Our paper was first written in Russian. Then we waited several months for permission to publish. And only after that did we start translating it. Fortunately Dr. Jim Feeney visited Moscow in early 1971 for a Varian instruments exhibition. We asked him to check our translation. He was very well known in Russia as one of the authors of a two-volume Russian translation of ‘High Resolution NMR’ and we were sure that half an hour would be enough for him to look over several pages. He did not hesitate to help us but after several minutes we saw that his face became thoughtful and anguished. After an hour we could wait no longer and asked what was the matter. Jim answered that all that time he had been thinking whether it was better to say ‘isotope effects’ or ‘isotopic effects’ ... and still could not solve this painful linguistic problem. ‘But it is interesting, you know’ he said, returning the manuscript to us, I suppose, with relief.

Soon after, many other publications appeared dealing with isotope effects on coupling constants. In 1972, Wojciech Stec was in our laboratory and agreed with our interpretation. In 1973, we met Bill Raynes from the University of Sheffield who made the first theoretical estimates of possible isotope effects for the coupling constants in the six isotopomers of H_2 .⁷ We agreed to continue these studies together, but for certain reasons (at that time I was not allowed to go abroad) it was delayed for almost 20 years! In 1975, Buckingham and Urland⁸ reviewed the theory of isotope effects and reproduced the ^{31}P NMR spectrum from our paper.⁴

Further investigations performed by Cynthia and Keith Jameson,^{9,10} Brian Bennett and Bill Raynes,¹¹ Rod Wasylshen,¹² Harald Günther,¹³ Hans Jakobsen,¹⁴ Jeremy Everett,¹⁵ Valerii Tarasov,¹⁶ and others involved many new types of spin–spin coupling constants including $J(^{19}\text{F}, ^1\text{H})$, $J(^{14}\text{N}(^{15}\text{N}), ^1\text{H})$, $J(^{27}\text{Al}, ^1\text{H})$, $J(^{69}\text{Ga} \text{ (and } ^{71}\text{Ga}), ^1\text{H})$, and $J(^{77}\text{Se}, ^1\text{H})$. Several attempts were made to explain trends in

isotope effects by using a geometrical approach. The idea was put forward that primary isotope effects may reflect the change in the bond length between interacting nuclei. The X–D bond is usually shorter than the X–H bond (according to many estimates $\Delta R = R(X-H) - R(X-D) \simeq 5 \times 10^{-3} \text{ \AA}$), so it was suggested that the primary isotope effect gives the value of the derivative $\partial J(X,H)/\partial R(X-H)$ as equal approximately to the ratio of ΔJ^P to ΔR . This means that in phosphorus compounds with P–H bonds the derivative $\partial J(P,H)/\partial R(P-H)$ is positive for four-coordinated phosphorus and negative for three-coordinated phosphorus.

The most serious difficulties were encountered when the well-known and practically important $^{13}\text{C,H}$ coupling constants were studied. The first experimental results gave a negative sign for the primary isotope effect and this was even supported by some theoretical calculations made for methane at the FP INDO level. However these results were later questioned and only recently has it been shown exactly that the primary isotope effect on $^{13}\text{C,H}$ coupling constants in methane, although still negative, is exceedingly small (less than 0.1 Hz) and that it is substantially less than the secondary one, i.e. paradoxically the stretching of the bond between the interacting ^{13}C and the proton (in the C–H₁ bond) produces less effect than the stretching of the bond between ^{13}C and a neighboring proton (in a C–H₂ bond). This was then successfully confirmed by ab initio calculations of $^{13}\text{C,H}$ coupling constants in methane by Raynes, Geertsen, and Oddershede.¹⁷ In 1990, I published a review on isotope effects on coupling constants.¹⁸ Currently we are studying halomethanes in order to find out more details about the nature of these isotope effects.

There are several reasons why isotope effects in NMR have been of interest for so many years. One is quite simple and obvious: NMR spectral parameters are at present the most sensitive molecular parameters available. They may therefore be applied to measuring the smallest perturbations of compounds under study and isotopic substitution is only the simplest example of such perturbations. There is also a permanent interest in isotope effects from the viewpoint of the theory of spin–spin coupling constants and chemical shifts. Such interest may be easily understood, as theoretical estimates of isotope effects give the first and often the last check of the theoretical approach. Finally, there is the possibility for an experimentalist in NMR to go into greater detail connected with isotopic variation, e.g., to study ^{13}C satellites, to compare data from ^1H , ^2H , and ^3H NMR, to observe effects due to heavy isotopes such as $^{35}\text{Cl}/^{37}\text{Cl}$ or $^{79}\text{Br}/^{81}\text{Br}$, and so on.

Nickolai M. Sergeyev. b 1938. B.S., 1961, Moscow Institute of Physics and Technology, Candidate of Physics and Mathematics, 1965, Department of Physics, Kazan University, Doctor of Chemistry, 1981. Professor, Moscow State University since 1993; Research work at the Karpov Institute of Physical Chemistry, 1964–68; NMR Laboratory, Department of Chemistry, Moscow State University, 1968–present. Royal Society Guest Research Fellowship, 1993–94, University of Sheffield, UK. Approx. 200 publications. Research specialties: analysis of high-resolution NMR spectra in liquids, dynamic phenomena and isotope effects, applications of NMR in organic and physical chemistry.

Shapiro, Bernard L.: The NMR Newsletter

Bernard L. Shapiro

Editor/Publisher, 966 Elsinore Court, Palo Alto, CA 94303, USA

The NMR Newsletter is an informal monthly publication that serves as a means of rapid exchange of information among active workers in the field of nuclear magnetic resonance spectroscopy. This field is defined broadly, and includes NMR results, techniques, applications, instrumentation, and theory. Magnetic resonance imaging and medical and biological applications are certainly included. (ESR, NQR, and other related fields are not encompassed except where a direct connection or relevance to NMR spectroscopy is clearly manifest.)

HISTORY

The *Newsletter* began in October 1958 as *MELLONMR* (*Monthly Ecumenical Letters from Laboratories of NMR*) at the Mellon Institute in Pittsburgh, Pennsylvania, before the merger with the Carnegie Institute of Technology to form Carnegie Mellon University. *MELLONMR* was created by Aksel A. Bothner-By and myself to facilitate communication with other laboratories about the problems and opportunities (there often seemed to be more of the former than the latter) in the then smallish NMR world.

At that time, the frontier of chemical NMR was the new 60 Mc (sic) CW spectrometer, Varian's HR-60 model, and Mellon Institute had the first such a marvel east of the Rockies. As difficult as it may be for today's NMR practitioners to imagine, the HR-60 was an unlocked, CW system using a large iron electromagnet. This spectrometer system lacked such amenities as a magnet cooling system, adequate thermal insulation, shim coils, a really reliable strip-chart recorder, etc., etc. The incorporation of computers and other items of digital technology were perhaps only dreamt of by a few visionaries. Multiple resonance, FT methods, and multidimensional NMR were not yet even on the horizon. Getting useful NMR data was a tedious, often frustrating business, and if one got decent numerical data on one small molecule in a day, that was a very good day indeed. Hence the need for mutual therapy with one's colleagues across the country, and hence *MELLONMR*.

In January 1964, the *Newsletter* went with me to the Illinois Institute of Technology in Chicago. *MELLONMR* became the less pronounceable *IIT NMR Newsletter*, but its nature was not changed. In August 1968, the *Newsletter* and I moved to College Station, Texas, with the same publication appearing as the *TAMU NMR Newsletter*. Beginning in early 1995, it continues privately as *The NMR Newsletter*. At present, the *Newsletter* is mailed out to subscribers in 34 states and 20 foreign countries. Three Nobel Prize laureates (so far) have been subscribers to the *Newsletter*, as have many researchers who have participated in the *Newsletter* for over 30 years.

From 1958 to 1967, the *Newsletter* was supported completely by the host institutions, Mellon Institute and the Illinois Institute of Technology. Growth of the *Newsletter* required a

wider financial base, and in 1967, external support was begun on a voluntary basis by over two dozen companies whose generosity enabled the *Newsletter* to continue without cost to the subscriber/participants. A modest subscription fee was started in 1969, and the further development of the *Newsletter* resulted in advertizing in the *Newsletter* beginning with the July 1972 issue. From that date, all *Newsletter* funding has come from advertizing, sponsorships, and subscription fees. Subscription rates have remained low to the present time because of the generosity and loyalty of the advertizers and sponsors, 10 of whom have supported the *Newsletter* continuously for over 20 years!

POLICIES

The general policies of the *Newsletter* have remained unchanged since 1958. *Participation* is the prime requisite for receiving the *The NMR Newsletter*. In order to receive the *Newsletter*, a subscriber must make at least occasional technical contributions to its contents. Since the subscriber/participant clearly is the best judge of what he or she considers interesting, the *Newsletter* contents are governed by the principle that 'We print anything'. (This is followed by the reservation, 'that won't land us in jail or bankruptcy court'.) With only a few exceptions, no editorial functions are performed. Technical material must, however, not have been published elsewhere. It is reproduced xerographically and disseminated exactly as submitted. Submissions are usually in the form of an informal letter, but this format is not required.

Another, very important operating policy is that of *nonquotation*: public quotation of *Newsletter* contents in print or in a formal talk at a meeting, etc., is expressly forbidden (except as follows), and reference to the *The NMR Newsletter* (and predecessors) by name in the scientific literature is never permissible. In order to quote results or use material from the *Newsletter*, it is necessary, in each individual case, to obtain the prior permission of the author in question and then to refer to the material quoted as a 'Private Communication'.

TECHNICAL CONTENT

The pages of the *Newsletter* encompass a very wide variety of subject matter, a sampling of which from just six recent issues includes chemical shift data and correlations for many nuclides, relaxation time studies, solid state investigations, instrumentation design and modification, software for analysis and presentation of data, spectrometer control strategies and tactics, new pulse sequences, kinetics of complex formation, pure theory of spin systems, spectroscopy and other studies of biologically interesting systems both in vivo and in vitro, a wide variety of imaging studies, binding to proteins and other biological macromolecules, quantitative analysis, polymer analysis, diffusion studies, multiple quantum spectroscopy, inverse detection schemes and applications, chemical shift calibration, probe design, chemical shift tensors, imaging of human stroke, coupling of HPLC and NMR, isotope effects, several uses of personal computers in the acquisition and processing of NMR data, pulsed gradient spin echo experiments, shaped pulses, etc.

Over the years, many new techniques have been introduced in the pages of the Newsletter. It was used as the first vehicle to show that magnetic resonance imaging was in fact possible. Many new examples of multidimensional NMR were shared in the Newsletter pages. In recent times, techniques and hardware for sensitivity enhancement have received much attention, as chemists strive to obtain useful spectra on smaller and smaller samples in less and less time (Boltzmann is still winning, but by orders of magnitude less than were the case only a few years ago). Two companies made their first results at 750 MHz known in the Newsletter pages. A major value of the Newsletter is the speed with which it communicates results in rapidly changing areas.

In addition to technical results (sometimes extensive and complete, sometimes fragmentary or preliminary), the Newsletter contains meeting notices and programs, book reviews, enquiries, mysteries, 'Positions Available (or Wanted)', 'Equipment Wanted (or Available)' notices, and occasionally, bits of humor, mostly intentional. Informality is encouraged.

Participation in the Newsletter is open to anyone, all around the world, and new subscribers are welcomed.

Biographical Sketch

Bernard L. Shapiro. *b* 1932. B.Sc., 1952, McGill University, Canada, A.M., 1954, Ph.D., 1957 (Chemistry), Harvard University, USA. Post-doctoral fellow with R. B. Woodward, 1956–58, at Harvard, where he was initiated into NMR spectroscopy by Aksel A. Bothner-By. Fellow Independent Research Program, Mellon Institute, Pittsburgh, Pa, USA, 1958–64; Associate Professor, Illinois Institute of Technology, Chicago, IL, 1964–68. Professor of Chemistry, Texas A&M University, College Station, TX, 1968–87; Professor Emeritus since 1987. Approximately 50 publications. Former research interests: geminal coupling constants, ring current effects, lanthanide-induced shifts. Since 1958, Editor/Publisher, *The NMR Newsletter* and predecessors.

Shaw, Derek: From 5-mm Tubes to Man. The Objects Studied by NMR Continue to Grow

Derek Shaw

GE Medical Systems, Ltd, Slough, UK

'NMR is worked out: move onto something more interesting.' That was the advice I was given by colleagues on finishing my Ph.D. in 1965. This seemed good advice at the time; NMR was giving new insights into molecular structure, but was slow and insensitive with very little potential for improvement. I did not take the advice, instead took a job in Varian's applications laboratory in the UK. Varian was the driving force of NMR at that time, and had an amazing group of people working in Palo Alto, Martin Packard, Warren Proctor, Jim Shoolery, Ray Freeman, Richard Ernst ... , the list goes on.

Then, as often happens, many things came together at the right time. In 1965 following up on suggestions made much earlier by Russell Varian, Wes Anderson and Richard Ernst showed that the concepts developed in 1822 by a former governor of Lower Egypt and friend of Napoleon (Jean Baptist Fourier) could be used to explain how the conduction of heat could speed up NMR! Minicomputers capable of performing the appropriate Fourier transformations in an acceptable period of time became available at a reasonable price, and the face of NMR changed for ever. There was much soul-searching as to whether the spectra obtained by this new method were the same as those that chemists had learned to work with from the traditional CW spectrometers. Fourier theory only works for linear systems, and NMR is not a linear system. There was therefore great concern, for example, as to how factors like chemical exchange manifested themselves with pulse excitation and hence affected the appearance of the final spectrum. Other concerns were the artifacts found in FT NMR, and there were many, particularly when a large dynamic range was involved such as in aqueous solutions; were they acceptable?

A major experimental problem with the current generation of homonuclear spectrometers was maintaining the field/frequency lock with pulse excitation. This issue was partially resolved and crude bolt-on accessories were produced for existing spectrometers such as the HA-100; some new systems, however, like the XL-100 (despite it being the first system to offer a deuterium lock), were not FT-compatible. Then in late 1969 the Bruker WH-90, an *FT-only* system, arrived on the scene and by the 'Pittsburgh Conference' of 1970, after a few months of panic development, there were acceptable FT accessories for the XL-100 and other leading NMR spectrometers. Fourier transform NMR had arrived. The added speed, and hence sensitivity, gave access to new proton applications, especially in the biological area. FT techniques also made other nuclei, especially ^{13}C , accessible; indeed, there was one school of thought that maintained that FT techniques were only useful for ^{13}C , being too artifact prone and unnecessary for proton work. They were wrong, and NMR never looked back.

The next radical development came about five years later when, in 1973, Paul Lauterbur showed that by using field gradients NMR could produce images. At the same period, X-ray computed tomography (CT) was revolutionizing medical imaging. X-ray images were no longer shadow graphs produced from a point source; they were images of axial slices. Radiologists had to rethink their view of anatomy! After a slow start and much pioneering work in the UK, e.g. in Nottingham where many competitive groups existed, and Aberdeen, NMR imaging started to produce recognizable images of human anatomy. Consequently, in the late 1970s, a radically new group of customers (radiologists) and companies (the diagnostic imaging manufacturers EMI, GE, Philips, Picker, Siemens, ...) became interested in NMR. The key factor at this stage was the magnet. Working, as I was at this period, for Oxford Instruments, was in some ways like being in an Alan Ayckbourne play. Diverse characters from all the medical imaging companies would come in to discuss their own 'secret ideas' and specify their own unique magnet requirements, resistive/superconducting, 0.15 T/1.5 T, four coil/ six coil ... These requirements were often the same as the company before, leading to the need for considerable 'political sensitivity'.

The early period of MRI, as it was now called (the N had disappeared so as not to frighten the patient, or to resolve a turf battle between radiology and nuclear medicine, depending on your perspective), was dominated by the 'field strength wars'. What was the best field strength for MRI? These battles were essentially commercial, science being used to justify the company competitive position. The resistive magnet soon fell by the wayside due to its inherent instability and low field strength, and the superconducting magnet became supreme.

One pawn in the field strength battle was in vivo spectroscopy. A major benefit of MRI over CT was to be tissue characterization, initially via relaxation time measurements. As it became apparent that there was not going to be sufficient specificity available via T_1 and T_2 determinations, MRS, as in vivo spectroscopy became known, was seen as a potential alternative. In vivo spectroscopy also had the potential to study metabolism; the noninvasive biopsy. MRS needed the highest magnetic field possible in order to achieve the best resolution of small chemical shift differences. This need, along with the higher signal-to-noise ratios achievable at higher field strengths (the truth, or otherwise, of this statement itself was the source of many, often violent, discussions) led, despite their extra costs, to the use of 1.5 T magnets in top-of-the-line systems. Without this push to high field, MRI systems might be quite different today, probably lower down on the cost/performance scale. MRS has made itself felt but has yet to become clinically accepted. There are still signs that this may happen ... soon.

In the space of a relatively short period of time, MRI has become a major medical imaging technique. It has excellent tissue discrimination, though perhaps not as much specificity as was hoped for and, as far as is known, is without significant hazard. It may well be that in the not too distant future MRI and ultrasound will be the dominant medical imaging modalities. NMR has already been recognized by two Nobel Prizes, one in Physics (Bloch/Purcell, 1952), and the other in Chemistry (Ernst, 1991); it would be rewarding to think that MRI would produce a third in medicine.

The development of MRI has dramatically changed the place of nuclear magnetic resonance in society. It is no longer

a remote scientific technique, it is a phenomenon the general public may well become aware of when they visit their local hospital. Indeed, many will be the 'sample' in an NMR system! The next stage will probably be the use of MRI in the operating theatre; minimally and totally noninvasive surgical procedures being planned with the aid of MRI data; and guided and monitored by real-time (EPI) imaging.

Performing surgical operations inside an NMR magnet is a far cry from working hard to build a magnet and probe large enough permit the use of a 5 mm instead of a 4 mm tube. It is a very brave person who will predict where the phenomenon of nuclear magnetic resonance will next impact on our lives. I do not have that courage.

Derek Shaw. *b* 1940. B.Sc., 1962, Ph.D., 1965, Chemistry, University of London. Worked for Varian Associates in NMR applications and marketing, 1968–78. Oxford Instruments Group marketing and product development [in vivo spectrometers (TMR)], 1978–83. GE Medical Systems working in MR imaging, 1983–present. Author of approx. 100 papers in various areas of magnetic resonance and a book on Fourier transform NMR.

Sheppard, Norman: NMR—Some Reminiscences

Norman Sheppard

University of East Anglia, Norwich, UK

My first acquaintance with nuclear magnetic resonance (NMR) was when, in late 1948, I visited the Chemistry Department of Harvard University on my way home after a year spent as a Visiting Assistant Professor at Pennsylvania State College (now State University). A friend of mine at Harvard, Gordon Stone, told me of this new technique which was thought to have promise for chemical structural identification. I was puzzled by this because it seemed to me that most of chemistry is related to the properties of the outer electronic orbitals, and that the role of the nuclei was essentially to act as charged point masses around which the electrons are arranged and move. But I had not anticipated the extremely high resolution of the new technique, soon to reach 0.5 Hz or nearly 10^{-10} cm^{-1} . This compares with 0.1 cm^{-1} which was the best routine resolution in infrared spectroscopy, the then most effective spectroscopic method for molecular structural determination.

Several years later I visited the Texaco Research Laboratory in Beacon, New York State, following a Gordon Research Conference on infrared spectroscopy. I had a mutual interest with Dr. Robert Eischens of Texaco in the infrared spectra of adsorbed molecules. At Beacon I was shown a Varian Associates' brochure which illustrated, I believe, the ^1H NMR spectrum of ethanol. From this I learnt of both the effects of differing chemical (electronic) environments on the resonance positions of a particular type of nucleus (the chemical shift), and the way in which spin–spin coupling fine structure in the resonances provides information about the presence of neighboring magnetic nuclei. Shortly after this I accepted the position of Assistant Director of Research in Spectroscopy in the University Chemical Laboratory, Cambridge. My teaching role in the laboratory was primarily to present molecular spectroscopy to the postgraduate chemistry students from the point of view of structure determination. I suggested to Professor A. R. Todd (later Lord Todd), Head of the Laboratory, that NMR would be a valuable addition to the existing UV–visible and infrared spectroscopic facilities. I recall that he obtained a (then 'huge') grant of £18 000 from the Wellcome Foundation in order to purchase our first ^1H 40 MHz Varian spectrometer. It was installed by Chris Dersch in 1957. I particularly remember this period because Professor Todd had told ICI of the impending delivery of the spectrometer. They had asked if they could bring a 'few' samples for study by this new technique, and I had agreed to this. However, I had not changed the proposed date of their visit even though the delivery of the spectrometer was delayed by several months. They arrived about a fortnight after the installation by which time Ralph Elsey, a senior technician, and I had only run a few samples of our own and were still mastering the technique of 'dishing' the magnetic field in order to obtain good resolution. The ICI scientists had brought

about 50 samples with them and expected the spectra to be interpreted as they came off! In fact it took us several months to run all their samples interspersed into the laboratory's own NMR program that soon became very active.

During the next few years NMR techniques developed rapidly through equipment initiatives taken by Varian Associates. The earlier very tiresome field drift was much reduced by a Super Stabilizer electronic device; resolution became optimized by cranking a handle to change the relative orientations of the magnet pole pieces rather than by 'dishing' the field; then sample spinning was introduced to average-out horizontal field inhomogeneities; and in due course (from Perkin-Elmer) 'Golay coils' enabled inhomogeneities in all three dimensions to be optimized by purely electronic means. Variable temperature operation and double resonance techniques all added to the power of NMR.

Jim Shoolery, in particular, played a vastly important role in acquainting the academic chemists with the use and value of the new techniques developed by the Varian engineers—and, of course, in persuading the chemists to purchase the new spectrometers or accessories! I recall with amusement a sales pitch that he was making at a meeting in Oxford when he pointed out that, although the cost of the latest 60 MHz spectrometer seemed to be very high, it was capable of providing the unprecedented resolving power of 1 in 10^9 . For comparison he pointed out that an optical telescope with such a resolving power would be able to resolve the images of two cats sitting side-by-side on the surface of the Moon. A voice with a strong Scottish brogue interrupted from the back of the lecture-hall, 'I don't believe there *are* two cats on the surface of the Moon!'

The impending arrival of the new NMR spectrometer led to strong interest amongst prospective research students who were graduating in Cambridge in 1957. My original NMR research team in that year consisted of Colin Banwell and Jim Turner from Cambridge and David Cohen from Canada. In 1959 they were joined by Robin Harris and Ruth Truscott (Lynden-Bell). It was also very helpful to have John Pople in the Chemical Laboratory as at that time he was interested in the theory of NMR. With Bill Schneider and Harold Bernstein, he later published in 1959 the then-definitive book on chemical applications of NMR.

Colin Banwell immediately got to work on a computer program for calculating NMR spectra from chemical-shift and coupling constant parameters using full symmetry factorization as developed by Harden McConnell.¹ The calculations themselves involved the use of the early EDSAC II computer in Cambridge which was subject to frequent malfunctions because of its dependence on the operation of banks of electron-tube valves. I had to go before the EDSAC Committee to justify our request for computer time. I recall the comment, after my presentation, 'That was very clear.' 'I think that this is probably the first time that I have really understood what a user wants to do!' Colin was very successful with his programming and used it to analyze the 'second-order' ^1H spectra of vinyl compounds, with that of the four-spin vinyl fluoride case as a *pièce de resistance*.²

The members of the group became very interested in the stereochemical as well as the electronic factors determining proton–proton coupling constants in hydrocarbon groupings. We helped to establish the planar zigzag interatomic pathway

as a generator of measurable long-range coupling constants across up to five bonds.³

Jim Turner's research project originated in an attempt to assess the sensitivity of our Varian spectrometer for detecting ^1H spectra. For this purpose, the single expected resonance from chloroform, CHCl_3 , was studied at high amplification. I then observed an 'extra' weak signal with about 1% of the intensity of the main resonance. I first attributed this to an impurity in the chloroform, until I realized that there was an identical second weak feature at the same distance on the other side. These were not caused by sample-spinning sidebands because they did not move with variations of the spinning frequency. It then occurred to me that this extra widely spaced doublet must arise from the 1% of chloroform molecules that have spin- $\frac{1}{2}$ magnetic ^{13}C nuclei rather than nonmagnetic ^{12}C ones. The separation between the doublet would give the value of the $^1J(^{13}\text{C},\text{H})$ coupling constant. In this case, the ' ^{13}C -satellites' had the same single-maximum shape as that of the 'parent' resonance. However in some other cases the satellites had a much more complex fine structure than did the parent resonance, and similar weak structure could be discerned at the foot of the latter strong single peak.

Second-order spectra are obtained when, as calculated in the same units of Hz, the chemical shift between two adjacent resonances is comparable to their mutual coupling constants. Under these circumstances intensity piles up preferentially in the center of the resulting spectral pattern. In the extreme case, when the chemical shift is zero for reasons of chemical (symmetry-related) equivalence, all the intensity resides in a single combined central peak. For this reason the ^1H nuclei of the methyl group of CH_3Cl , for example, give a single combined resonance without features that can be used to derive a value for the magnitude of the proton-proton coupling constant.

However the large separations caused by the $^1J(^{13}\text{C},\text{H})$ coupling constant act as an 'effective chemical shift' and lead to the generation of spin-spin fine structure reflecting the presence of otherwise chemically equivalent ^1H nuclei attached to an adjacent nonmagnetic ^{12}C nucleus. Hence, the ^{13}C satellites provide accessible coupling constant data which are not available from the spectra of the great majority of molecules with only ^{12}C nuclei.⁴ Since it is the important type-molecules, such as acetylene, ethylene, ethane, or benzene, that have all their ^1H nuclei chemically equivalent for reasons of symmetry, the extra information available from analysis of the ^{13}C satellites is particularly valuable.

Jim Turner investigated the NMR spectra from a series of substituted ethanes and related cyclic compounds with a view to determining the dependence of the vicinal $^3J(\text{H},\text{H})$ coupling constants across the central CC bonds on the azimuthal angle between the CH bonds. The ^{13}C -satellite technique was particularly valuable for determining the coupling constants between chemically equivalent ^1H nuclei in $\text{XCH}_2\text{CH}_2\text{X}$ groups as in 1,2-dichloroethane and the cyclic molecule dioxane.⁵ The collected results helped to provide the experimental basis of the 'Karplus rules',⁶ subsequently used very widely in determining the conformations of large ring-containing organic molecules.

David Cohen found that he could only reproduce some complex second-order spectra from dichloropropenes theoretically if he made the assumption that certain coupling constants were

of opposite sign from others.⁷ This was an unexpected discovery that received subsequent quantum-mechanical explanation. Another laboratory made this discovery independently at about the same time.⁸

Robin Harris initially followed Jim Turner's conformational interests but using perfluoro compounds.⁹ In his Ph.D. thesis, he then studied the temperature dependence of the spectrum of cyclohexane.¹⁰ At room temperature a single observed resonance denotes the chemical equivalence of all the ^1H nuclei, brought about by the rapid chair-to-chair inversion of the carbon skeleton on the NMR timescale, i.e. inversion at a rate greater than the chemical shift difference in Hz between axial and equatorial H atoms. Cooling led to the generation of much more complex spectra when the observable chemical shift between these two types of environment in turn led to the manifestation of many $^3J(\text{H},\text{H})$ splittings. The parameters determining the inversion process itself were derived from the series of temperature-dependent spectra.

Ruth Truscott synthesized isotopic forms of ethane, ethylene, and acetylene containing one or two ^{13}C nuclei, respectively. Analysis of the NMR spectra gave complete coupling-constant data for these fundamental type-molecules, including the evaluation of $^1J(^{13}\text{C},^{13}\text{C})$ coupling constants for the first time.¹¹ The magnitudes of the $^1J(^{13}\text{C},\text{H})$ couplings correlated very well with the s character of the respective carbon orbitals, i.e. contact terms were clearly dominant within the coupling mechanisms. The $^1J(^{13}\text{C},^{13}\text{C})$ data were more complex but have probably since been accounted for by ab initio calculations.

The Varian spectrometer was, of course, purchased primarily for use in molecular structure determination, or structural diagnosis as some people refer to it. In fact it soon became very effective in this respect and made important, sometimes decisive, contributions to settling the structures of natural product molecules such as gibberellic acid¹² (a plant hormone that promotes rapid and extensive growth), the alkaloid calycanthine,¹³ and the erythroaphins derived from the coloring matters of the aphid group of insects.¹⁴ My role was to advise the chemists concerned on the interpretation of the NMR spectra; the erythroaphin case was instructive in putting the large chemistry effort back on course after a misinterpretation of an earlier chemical step. Over this period NMR brought about a revolution in Cambridge in the effectiveness of structure determination of medium-sized organic molecules, of inorganic coordination compounds with unusual ligands, and particularly of large molecules in the natural product field.

Before I left Cambridge for the then new University of East Anglia in 1964, the systematic teaching of structure determination by spectroscopic methods had moved from the post-graduate to third year undergraduate level. The latter students were presented with UV/visible, infrared, and NMR spectra of the 'unknown' organic compounds given to them for analysis.

The great success of NMR in structural diagnosis led to a consideration of the desirability of recording spectra in a standard format on printed charts. Up to that time, each spectrum had to be calibrated with sidebands because of field drift, etc. The advantages of such a situation were urged on Perkin-Elmer Limited (the UK offshoot of the Perkin-Elmer Corporation of the USA) by a panel of spectroscopic consultants that included Rex Richards, H.

W. (Tommy) Thompson, and myself. It was concluded that a permanent magnet-based spectrometer would be expected to have minimum field drift and also be economical in operational costs. Perkin-Elmer Limited therefore developed such a 40 MHz spectrometer which was installed in Cambridge for my evaluation. Although this was very successful, its development into quantity production was slow, doubtless partly because NMR was a new and unfamiliar technique to the parent corporation. As a result, Varian Associates were the first to realize this aim by marketing the well-known A-60 routine spectrometer. However Perkin-Elmer spectrometers were marketed in due course and later developed up to the feasible permanent magnet limit of 90 MHz for ^1H nuclei. For research purposes the Varian HA-100 was the workhorse for many years. Subsequently, as is well known, much higher magnetic fields, now up to the equivalent of 750 MHz for ^1H , have been achieved using superconducting magnets, many of them produced by Oxford Instruments Limited following encouragement to move into this field from Rex Richards. The major advances of pulse techniques coupled with Fourier transform analysis, the improved spectral separations and sensitivities from the use of high magnetic fields, and the 2D procedures for spectral analysis developed by Ray Freeman, have together caused NMR to become extremely effective in studying the large molecules of biochemistry, such as enzymes and proteins, in general in solution, again with encouragement from Rex Richards in the UK and from others elsewhere.

Originally the organic chemists, having benefited from the success of ^1H NMR, considered that Nature had been most uncooperative in making the abundant isotope of carbon, ^{12}C , nonmagnetic. Clearly, much additional and important structural information could be derived, in principle, from spectra of the magnetic isotope ^{13}C , but unfortunately it is only 1% abundant and gives much weaker signals than ^1H on a nucleus-for-nucleus basis. However they had underestimated the capability of technologists for reaching a difficult objective if the need is compelling. In the early 1970s the use of pulse rather than continuous-wave methods produced FT spectrometers which suddenly made the production of ^{13}C spectra routine. These developments were responsible for Richard Ernst's recent Nobel Prize. It then became apparent that, in fact, the organic chemists have the best of both worlds, i.e. readily obtainable spectra which are sufficiently simple that they can be interpreted even from very highly complex molecules. With hindsight, even the ^1H spectra that provided the original great stimulus to the development of NMR would have been very much complicated if all the carbon nuclei had been magnetic. In that case, NMR spectroscopy might have stayed as the province of professional spectroscopists capable of analyzing only the spectra from small molecules. Instead NMR has developed into one of the best spectroscopic methods for molecular structure determination—the very best one for organic and biochemistry.

When I moved from Cambridge to the University of East Anglia in Norwich, UK, to help in the foundation of the School of Chemical Sciences, I carried my NMR interests with me and two other of our newly appointed teaching staff, Robin Harris and Kenneth Packer, also had strong interests in this area. I vividly remember our new HA-100 spectrometer being installed by crane in our one-storey temporary building after removal of part of the roof! I continued to carry out a number of NMR studies in a variety of directions of chemical

interest, including studies of the solvation shells of metal ions in solution, conformational isomerism, and an evaluation of the potential of ^{17}O spectroscopy. However my principal research interest moved into the direction of the spectroscopy of adsorbed species on catalysts and here NMR had inadequate sensitivity and vibrational spectroscopy was more effective. NMR is still marginal in this respect but is ripe for further progress. However Robin Harris and Ken Packer both made excellent careers in NMR and later, in collaboration, became very well known for their joint development of techniques for obtaining high-resolution NMR spectra in the solid state. In my Cambridge days I had dreamt of overcoming the large linewidths in the spectra of solid samples by spinning powdered samples in spherical plastic ampules with wavy fins driven at high speed within a centrifuge at the sample position! Luckily, spinning very rapidly about a fixed axis at the 'magic angle', as suggested by Raymond Andrew, provided a technologically more feasible route to the same end!

Although I am no longer an 'NMR man', I have remained very highly impressed by the continuing development of versatile experimental and theoretical methods within its field (confines is hardly the right word). To my mind NMR provides a very fine example of the way in which a new idea or experimental technique in science can disseminate itself in many unpredictable but profitable directions. The physicists who did the first successful experiments, Bloch at Stanford and Purcell at Harvard, were interested in the magnetic resonance phenomenon from the point of view of determining the magnetogyric ratios of the nuclei themselves. When high-precision experiments led to slightly different resonance frequencies for the same type of nucleus in different chemical surroundings, the phrase 'chemical shift' was coined, probably as a physicists' swearword! After all, even more precise measurement on bare nuclei were much more difficult to envisage! Applications of this physicist's swearword in due course led to a technique without which the frontiers of chemistry would be much less far-flung than they are today. Even more recently, NMR imaging (with the N for nuclear missed out because of possible misunderstanding by the public) as envisaged by Paul Lauterbur and developed by Peter Mansfield and others, has become a major aid to whole body medical diagnosis.

NMR therefore provides an excellent example of the unity of science and of how the solution of long-standing needs or problems can come from seemingly unrelated directions. But, as in the case of NMR, the applications tend to become apparent only several decades after the original discovery (one and a half decades for NMR in chemistry and four decades in medicine). Unfortunately, it is difficult for politicians and the public to take into account such timescales (for politicians their own timescale is about five years, i.e. the intervals between elections; for financiers interested primarily in next year's profits the timescale is one year). There is therefore a real danger that curiosity-oriented research, which is the mainspring of new science and new technology, will be allowed to wither on the vine for lack of adequate financial support.

I would like to end with a tribute to the Varian brothers, their engineers, and their chemistry front-man, Jim Shoolery, for all they did to develop the techniques of NMR and to draw the attention of the academic chemists to their many fruitful applications.

Biographical Sketch

Norman Sheppard. *b.* 1921. B.A. (Chemistry), M.A., Ph.D., Cambridge University, UK. Assistant Director of Research in Spectroscopy and Fellow of Trinity College, Cambridge, 1955–64; Professor of Chemical Sciences, University of East Anglia, Norwich, UK, 1964–86, now Emeritus Professor. Approx. 300 publications. Research specialties: vibration spectroscopic and (formerly) NMR studies of molecular structure and dynamics, with particular application to the identification of chemisorbed species on catalyst surfaces.

Shoolery, James N.: High-Resolution NMR: A Dream Come True

James N. Shoolery

Varian Associates, Palo Alto, CA, USA

NMR began in a rather unusual confluence of events, people, and visions. World War II, with its demand for synthetic materials, had focused attention on the limitations of contemporary instrumentation, and by 1946 the first commercial infrared spectrometers were available. In addition, the war also accelerated the development of electronics, including radar, which opened up new possibilities of analytical techniques.

Coincidentally, the klystron tube, which made airborne radar possible, played a role in the early development of NMR. The klystron was invented by Russell and Sigurd Varian, who firmly believed that scientific innovation should find practical applications. While developing the klystron for air navigation and defense, they, together with their friend, Stanford University professor William W. Hansen, began dreaming of having a laboratory of their own.

When the war ended, Hansen returned to Stanford, where he contributed to Felix Bloch's original paper on nuclear magnetic resonance. E. M. Purcell studied the same phenomenon independently at Harvard University and shared the 1953 Nobel Prize for Physics with Felix Bloch for that work. The Harvard group developed a considerable body of theoretical and experimental work but did not participate in the commercial development. Some months later, Russell arrived at Stanford as a Research Associate and quickly saw the potential applications for the new phenomenon. On December 23, 1946, at Russell's urging, Bloch and Hansen signed a patent application and gave an exclusive license to 'Varian Associates', the laboratory the men had envisioned, to develop commercial applications of the nuclear induction device.

In January 1948, Varian Associates actually came into existence. From the beginning, the company was diversified into two products lines: the klystron tube with rapidly growing markets and mature manufacturing techniques, and nuclear magnetic resonance devices with no markets and no manufacturing techniques. The income from the klystron made it possible to nurture the emerging technology during its infancy.

At Stanford, Bloch and his group, working with an improved electromagnet, found that different liquids yielded different values for the proton magnetic moment. The shift in the field at the nucleus, due to screening by orbiting electrons, interfered with accurately measuring nuclear moments. Accordingly, or so the story goes, the physicists christened that irritating obstacle *the chemical shift*.

Varian Associates clearly needed a homogeneous electromagnet for their research into chemical applications. To help pay for building it, the company offered the magnet as a product and issued a data sheet, which, when I came across it, changed the course of my career. I began my university studies in 1941, but in early 1944, the US Navy turned me into a radar technician, a job that gave me a thorough grounding

in electronics. The subject of my graduate studies at Caltech was microwave spectroscopy, and in late 1951, as a postdoctoral fellow, I was asked to look at the suitability of Varian klystrons for the microwave spectrometer. At a trade show, I came across Varian's specification sheet for the 12-in. electromagnet and an accompanying stack of reprints of a Letter to the Editor that had appeared in the *Journal of Chemical Physics*.¹

When I saw the three peaks of ethyl alcohol, I knew what I wanted to do and where I wanted to do it. I wrote to Varian, suggesting that a company far-sighted enough to offer such a technologically advanced product might consider employing a chemist to help develop applications for their instrument. I modestly announced that I would be available. To my delight, Varian Associates offered me the position.

NMR SPECTROSCOPY: IN THE BEGINNING (1952–60)

I reported for work in April 1952, and my badge, number 512, reflected the intimacy of the company. Two members of the Stanford group—Martin Packard and Emery Rogers—were already part of the Varian team; two more, Wes Anderson and Jim Arnold, joined shortly after my arrival; and another two, Warren Proctor and Harry Weaver, somewhat later. (Much later, Ray Freeman, Richard Ernst, and Howard Hill arrived.) Not only was there the excitement of working on the leading edge of a technology, but the Varians had created a unique atmosphere. Russ and Sig, shown in Figure 1, visited the technical projects on almost a daily basis to

Figure 1 Russell Varian (at left) and his brother Sigurd with a klystron tube in the early 1950s

discuss, suggest, and encourage, treating every employee with consideration and respect.

By the time I arrived, a research and development (R&D) group was already working on the first order for a 30 MHz high-resolution instrument with a magnetic field strength of 7050 G, able to resolve the three peaks of ethyl alcohol. Martin Packard, who as a graduate student had built Bloch's original apparatus, headed the team. Emery Rogers was readying the power supply for the magnet. My first job was to design and build the radiofrequency (rf) unit. My second task, in September 1952, was to install the first commercial instrument, the HR-30, in the Humble Oil laboratory in Baytown, Texas.

In January 1953, I happily opened the Varian Applications Laboratory, the Applab as we called it, for business. We had already resolved the fine structure from chemically nonequivalent protons in molecules and even hyperfine structure from spin-spin interactions between nonequivalent nuclei, but there was a very limited theoretical basis for interpreting the new spectra. My next assignment was to establish the empirical relationship between observed spectral features and the molecular structure of the sample. I felt as if I'd died and gone to heaven.

The Applab HR-30 was the state-of-the-art, top-of-the-line nuclear magnetic resonance spectrometer. However, it had a few drawbacks. Its 5400-lb. electromagnet required cooling water and heavy-duty electrical service as well as a very substantial floor. The finer details of the spectrum were apt to vary with the instability of the magnetic field. Sensitivity was so poor that only neat liquids or concentrated solutions would produce signals visible above noise, and at the 7050 G field strength the 10 ppm range of the proton spectral dispersion severely limited the interpretability and usefulness of the spectra.

In addition, it was an operator's nightmare, as can be seen in Figure 2. After locating the signal from a sample of water, the operator had to place the probe (which contained the rf coils and sample) in the homogeneous spot in the magnet. That spot changed its shape, size, and location with changes in temperature and with the effects of hysteresis caused by turning the magnet on and off. When the oscilloscope finally displayed a satisfactory pattern, the sweep width had to be calibrated by generating audiofrequency sidebands of the water signal. Making a permanent record of the data meant taking two Polaroid photographs of the oscilloscope screen, one to establish the reference point of the chemical shift of water, and then, quickly, before the field could drift very far, another of the sample being studied.

Yet, we were excited about presenting the HR-30 to the scientific community. Trying to avoid the ominous word *nuclear* and wanting an acronym, Emery Rogers, the newly appointed marketing manager, and I decided to call the new technique NMR spectroscopy and used that term at every opportunity. As soon as possible, we moved from photographs to high-speed chart recordings. The charts presented the NMR spectrum in a format closer to that of the popular infrared (IR) spectrometers, displaying a magnetic field scan in parts per million (ppm) where IR displayed a wavenumber scale. To differentiate the two techniques, we displayed NMR spectra as peaks with a positive rather than negative deflection. (The choice, we claimed, symbolized the vitality of the new technique.) We referred to the fine structure arising from

Figure 2 The author and Virginia Royden operating the HR-30 Applab instrument in about 1954

spin-spin coupling as a *multiplet* rather than an absorption band. (Some years passed before all our ideas were adopted.)

In July, 1953, Emery and I began publishing *Technical Information from the Radio Frequency Laboratories of Varian Associates*, which we sent to the chemistry departments of major universities and the research departments of large chemical companies. The *Technical Information Bulletin*, as it came to be known, appeared, liberally illustrated with spectra, whenever new developments occurred. A few months later, we began a monthly advertisement in *Analytical Chemistry*, titled 'This is NMR at Work', which rigorously described and illustrated a recent example of Applab work.

A year passed before I found an example showing that NMR could solve a significant problem that other more established techniques could not. In mid-1954, E. J. Corey, then working at the University of Illinois, submitted a sample of cycloheptatriene. Neither IR nor UV analysis could unequivocally identify its structure, but our NMR spectrum did so with simplicity and directness.

Daily exposure to the limitations of the HR-30 turned me into a product champion, or as Emery Rogers generously put it, 'a chemist with an antipathy to accepting horizons as they seem to be'. With encouragement from Russ and Sig, the 18 months between mid-1954 and 1956 became an orgy of product development. In rapid succession, the Varian R&D group produced higher field strength, sample spinning, field gradient shimming with electric currents, and magnetic flux stabilization.

Since chemical shift dispersion increases linearly with magnetic field, and sensitivity increases as the $\frac{3}{2}$ power, I welcomed the news in 1954 that the power supply could deliver enough power to the magnet to operate continuously at a field strength of 9400 G, sufficient for operation at 40 MHz. In 1955, Varian introduced the HR-40, which, in addition to its increased power, was equipped with a sample spinner, a device that represented a major breakthrough in the quality of resolution. Work by Arnold and Anderson in Bloch's laboratory at Stanford had shown that spinning the sample with a small air turbine narrowed the NMR lines in liquid samples by averaging the magnetic field over a circular path.²

At that time, altering the distribution of field gradients meant loosening the main bolts holding the pole pieces to the yoke and inserting or removing a metal shim. The group at Stanford had experimented with current-carrying coils on the pole faces to modify the distribution of magnetic flux, but the correcting currents were difficult to adjust because they were highly interactive. Varian R&D solved that problem through mathematical analysis. Adjustment of homogeneity with electric shims, while still requiring some expertise, became a systematic procedure.

Before magnetic flux stabilization was developed, obtaining a spectrum was like looking through binoculars at a row of birds on a telephone wire from the back of a truck bouncing over a rutted road. The regulation of the magnet current was, at best, about 1 in 10^7 , while we needed a field stable to 1 in 10^8 or better. When we heard that a group at Princeton was using degenerative feedback to attack the problem, we attached a pick-up coil to one of the magnet pole pieces. Any change in the field, even 1 in 10^9 , induced a few microvolts across the coil and resulted in a minute current in a galvanometer. The deflection was amplified by a light beam reflected off a mirror attached to the suspension. A split photocell detected the change, and fed back a current to oppose the change.

I remember my first trial of the device in 1956. Closing the switch made it seem that I'd gotten out of the truck and mounted my binoculars on a tripod. I could easily count the birds on the wire and even tell if their feathers were ruffled. In a fit of enthusiasm, we called the device a Super Stabilizer. Offered as an accessory that could be retrofitted to earlier spectrometers, it had the same effect on the acceptance of high-resolution NMR as the double-beam principle had had on IR. Field jitter and slow drift were largely overcome, and NMR spectra became more reproducible.

Having stabilized the electromagnet, it made sense to capitalize on its superior field strength. Operation at 60 MHz (14 096 G) represented a 50% increase in chemical shifts and a doubling of sensitivity. The many metallurgical problems of manufacturing pole caps with predictable high-resolution performance at that field were solved, and a curved profile was developed that produced a much larger homogeneous region in the magnet gap.

The HR-60, announced in 1958, was a commercial success, but more important, it demonstrated what we at Varian so firmly believed: that overcoming the sensitivity and spectral complexity problems would open up unlimited applications of NMR in chemistry and biochemistry. Invitations to make presentations to ACS sections, Gordon Conferences, and analytical chemistry meetings increased, and in October 1957 we held the first annual workshop to introduce the mysterious new technique to chemists. I estimate that by 1960, I had described the principles of NMR to about 20 000 people at home and abroad.

As interest in NMR spectroscopy increased, Emery and I began planning to demonstrate a spectrometer at an instrument exhibit. In 1957, having attended the 9th Pittsburgh Spectroscopy Conference, held on the 11th floor of the William Penn Hotel in Pittsburgh, we decided to take a space for 1958. We were told that the only remaining one big enough for a monster like ours was in the hallway adjacent to the elevators. The location was deemed undesirable because of the traffic there, but the price was right. We booked it and the next year brought an HR-60 to display.

Getting a 5400-lb. magnet to the 11th floor in an elevator was an exciting project. Persuading the hotel to provide cooling water and three-phase 220V power added more challenges. Then, at the moment of truth, our instrument exhibited unexpected instability. Our electronics wizard Forrest Nelson quickly solved the problem by moving the magnet away from the elevators, whose arrival and departure was perturbing the field. The location of our site turned out to be a great asset. Everyone using the elevators passed by, and most stopped to look and talk. Over the next years, the Pittcon booth contributed greatly to an expanded awareness of NMR.

Once the 60 MHz magnet was developed, we set our sights on the highest practical field an electromagnet could reach. Magnetic saturation of the iron set a limit of 100 MHz (23 490 G). The HR-100, introduced in 1959, had resolving power better than 1 part in 10^8 . Astronomers with a telescope of equal power would be able to see two cats on the moon sitting 1 ft. apart.

From the outset, NMR spectroscopy enjoyed a fundamental advantage for quantitative work: unlike UV-visible and IR spectroscopy, which must take account of differing absorption coefficients, the NMR signals being compared arise from the same spectroscopic transition. If there were no drift, the total area under the peaks could be compared. Unfortunately, the stability of the dc amplifiers introduced large errors in the integrals. In 1959, we solved the drift problem with an NMR integrator, which sinusoidally modulated the magnetic field and selected the ac signal components, while suppressing the sidebands with a balanced phase sensitive detector. In 1960, I showed that NMR signals from chemically shifted protons could be compared with an accuracy of 1% or better using this approach.³ Now NMR could match abilities with other analytical instruments.

In 1955, we realized that the long lifetimes of nuclear spin states would allow the chemist to tamper with the energy levels of a coupled system and deduce which nuclei share common energy levels.⁴ Those showing coupling must be located in atoms that are close neighbors in the molecular structure. All we needed was a way to irradiate only the protons having a particular chemical shift. In 1961, a minor modification of the NMR integrator and the addition of a variable frequency audiooscillator made selective irradiation a routine matter.

By 1957 the necessary infrastructure was in place for a significant leap forward. With the aid of the R&D group, Emery Rogers and I developed a proposal to build an affordable, reliable, conveniently sized, proton-only spectrometer with high stability and sensitivity. Some of our specifications were so far from realization that meeting them seemed to require a miracle. But we believed in miracles and had faith in ourselves and our co-workers. So did Varian Associates, which funded the four-year project, code-named ASP. (That was not a symbol for a venomous attack on competitors, who were beginning to appear by then, but rather an acronym for the project schedule: As Soon as Possible.) We called the instrument the A-60, A for analytical, 60 for the frequency and our hoped-for year of release.

Our specifications called for a much smaller electromagnet styled to fit into a laboratory environment. An attractive, user-friendly console with logical groupings of controls would have a flat-bed recorder for producing the NMR spectrum, for the first time, on a precalibrated chart. The instrument was to scan the entire proton NMR spectrum and be able to reproduce

Figure 3 The A-60 spectrometer, introduced in 1961

it within the pen width on the chart. Sensitivity had to meet current standards, but the instrument still was to be simple and reliable. And all of this was to cost little more than the better IR instruments then offered.

Precalibration required locking the frequency to the magnetic field, a tough technical challenge that was solved in an ingenious way. A small sample of water in the probe near the analytical sample was irradiated at 60 MHz and modulated by an audiofrequency generated by closing a loop to create a nuclear sideband oscillator, or NSBO as it was called. The circuit would only oscillate at a frequency that placed the sideband exactly at the water resonance line frequency. The rapid response of the device lessened the demands for stability on both the power supply and the flux stabilizer.

The final test of the prototype, introduced at the 1961 Pittsburgh Conference, is a particularly happy memory. I put a sample into the instrument, adjusted the resolution, and ran a spectrum on the precalibrated chart. It was perfect. But could the A-60 reproduce a spectrum with the fingerprint quality of the IR? I moved the pen back and restarted the scan. Momentarily distracted, I looked back and saw only one line on the chart. 'Why didn't the second scan run?' I asked. The answer came back, 'It did'. Amazed, I returned the pen three more times. The five spectra were a single trace on the paper. At that instant, I knew that organic chemistry would never be the same.

We decided that if chemists became familiar with a standard format for the NMR spectrum, they would develop a feel for the interpretation. To that end, we prepared a two-volume catalog containing 700 spectra of a carefully selected variety of chemical compounds, which became the laboratory companion of thousands of organic chemists.⁵ Exceptionally reliable and sturdy (see Figure 3), the A-60 became the analytical tool of choice to follow the progress of synthetic work and to analyze the structures of synthetic and natural products. NMR had come of age.

THE 1960S: DECADE OF THE TECHNOLOGICAL BREAKTHROUGHS

With the widespread demand for the A-60, Varian's instrument division grew rapidly. Emery Rogers, the new

general manager of the instrument division, persuaded me to take over the marketing, which, for my five-year tenure, consisted mainly of informing chemists of the growing ability of high-resolution NMR to solve their problems.

The market for NMR spectrometers merited the establishment of an European Applab. Set up in 1962, in Zürich, Switzerland, under the direction of Warren Proctor, the new Applab acquired such an enviable reputation that scientists from all over Europe fought for places at its annual NMR workshops. An Eastern Applab was established in Pittsburgh, after Emery and I noticed on one of our trips that space was for rent in the Pittsburgh Airport Terminal Building. The location turned out to be an inspired choice. It became a stop on scientists' annual pilgrimage to the Pittsburgh Conference and, later, to the Experimental NMR Conference (the ENC) at the Mellon Institute.

In 1965, Emery Rogers and I collaborated in our last project. It began after one of the workshops in Zürich, when we were strolling the streets discussing a replacement for the A-60. Although still the best instrument of its kind, the vacuum-tube technology and electromagnet of the A-60 were becoming obsolete. We stopped in a tearoom, roughed out the concept for a permanent magnet replacement, and christened it the T-60, in honor of its origin. The T-60, introduced in 1969, became the workhorse of organic chemists. Its rugged design and reliability resulted in its widespread use in teaching and research. Many of the instruments are still operating after more than 20 years of service.

During most of the 1960s, the instruments in the Applabs changed little in terms of their power, but they did become more stable and easier to use. (In spite of my five-year sojourn in marketing, I managed to publish nearly 60 collaborative papers during the 1960s.) Increasing use was made of quantitative measurements and spin decoupling. Knowledge about spin-spin couplings, chemical shift effects, ring current effects, solvent shifts, second-order spin-coupling effects, dependence of coupling on stereochemistry, effect of chemical exchange, and other phenomena grew rapidly. Varian sponsored NMR workshops and courses in the United States and Europe on a regular basis in order to spread the new knowledge.

There was also a greatly improved product to discuss. During the 1960s, several major developments took shape in research and development. The first arose from the need for better stability in the HR-100. The field/frequency lock system of the A-60, with a separate lock sample located near the observing coil was considered, but there wasn't enough room for it in the HR-100 gap. The solution was to lock the spectrometer (using a feedback loop) on the tetramethylsilane peak, always present in the sample for reference purposes, and to generate a sideband, frequency-swept through the spectrum in a linear fashion. That internal lock was more stable over time than the external lock of the A-60 and was the forerunner of the lock systems in use today. Systems equipped with this accessory were called HA-60 or HA-100.

The second breakthrough was made possible by the commercial availability of superconducting niobium-titanium alloy wire. Varian recognized the opportunity to gain the benefits of increased field strength. Research physicist Harry Weaver designed a high-resolution solenoidal magnet wound from the new wire that, unlike most superconductors, could remain superconducting in a strong magnetic field. The

completed solenoid, based on a mathematical analysis of the flux distribution, achieved resolution comparable to iron magnets. In the persistent mode, with current circulating in the resistance-free solenoid and through a superconducting return path, the stability was exceptional.

We exhibited a spectrometer at the 1962 Pittsburgh Conference with a frequency of 220 MHz. Interest was high, but because of the cost and the difficulties and expense of using liquid helium, buyers were few. The high field gave greater spectral dispersion and more sensitivity, but the improvement was not sufficient for entirely new applications. Nevertheless, research and development went forward on a 300 MHz system based on a multifilament niobium–titanium wire, and the HR-300 was announced in 1967. Although Varian Associates pioneered superconducting magnets for NMR in the early 1960s, the full benefit of those amazing devices was not realized until the 1970s. The breakthrough had been achieved, however, and the days of the electromagnet were numbered.

In 1964, Leland Allen, then at Yale University, brought to our attention a *computer of average transients*, or CAT, being used to study minute electrical transients in biological systems. An initiating stimulus was applied n times, each time sampling the transient response voltage at a high repetition rate, storing the consecutive digitized values in a 400 channel memory, and adding each set of samples to the values already stored. The transient signal increased by the factor n , while random noise increased as the square root of n .

We derived a trigger for the scan from the reference peak in the spectrum and tried out the device in the Applab. The CAT showed the expected improvement in weak signals, and Varian commissioned the Nicolet Company to develop a commercial version, which became the C-1024 accessory. That device was the first application of digital data processing to NMR, a breakthrough that ultimately revolutionized NMR and chemistry.

The most dramatic breakthrough of the 1960s was the demonstration of an apparatus that acquired information simultaneously from all of the nuclei in the sample and obtained the spectrum through digital Fourier transformation of the data. Although Hahn reported pulsed excitation in 1950, and Lowe and Norberg reported the Fourier transform (FT) relationship between the impulse response and the spectrum in 1957, Richard Ernst was the first to combine them in an experiment in 1966. At that time Ernst was working in Wes Anderson's research and development group at Varian. Solving chemical problems in the Applab, I witnessed the milestone efforts going on across the hall. None of us realized then how much FT NMR would change chemistry and instrumentation, nor that Richard Ernst would receive the Nobel Prize in 1991 for that work.

Varian had provided an especially receptive climate for the discovery. Russell Varian planted the seeds in 1958 with a patent application for wideband excitation and Fourier analysis, but no suitable wideband source readily came to mind. Russ urged those of us involved in NMR development to try irradiating the sample with white noise, but we were so set on getting rid of noise that the merits of his idea were lost in our fixation on the more immediate goal. Wes Anderson was already developing a design for multichannel excitation and detection, but the unwieldy approach was crying out for new inspiration. Cross fertilization of ideas occurred when Richard, fresh from his doctoral work in Switzerland, joined

Wes's research group. His work led to a practical way to excite a broad band of frequencies by using a pulse of rf power, followed by digitization, time-averaging of multiple pulses, and finally, Fourier transformation.

The experiment worked as predicted, reducing data acquisition time from hours to minutes, and improving sensitivity between 10- and 100-fold. In 1966, the only computers capable of handling Fourier transformation were mainframes that needed punched card or paper-tape input. Varian's accounting and management information systems provided overnight services when computer time was available. A truly useful FT NMR instrument awaited the development of a minicomputer dedicated to the spectrometer.

In 1965, the internal lock system of the HA-60 encouraged us to investigate the ^{13}C nucleus, long of interest in spite of its low abundance (about 1%) and its weak magnetic moment. (Lauterbur's early work using adiabatic rapid passage had not seemed an attractive routine method.) Scanning the ^{13}C spectrum very slowly at low rf power, we could see the multiplet structure of the ^{13}C signals due to C–H coupling in a single scan of a 10 mm sample of neat ethanol. We found that the loss in sensitivity due to further splitting by long-range CH coupling could be recovered by strong irradiation at the proton frequency and observed an Overhauser enhancement of approximately three for the carbon peaks. That work was published as a *Varian Bulletin* but was not followed up by systematic studies.

We had accomplished our objective, however: J.D. Roberts commissioned a custom ^{13}C instrument with a synthesized frequency sweep that could scan more slowly and register successive spectra perfectly for time averaging. With that instrument, he and his students laid the foundations for the widespread adoption of ^{13}C NMR by the organic chemists. Some of the instrumental concepts found their way into the design of the XL-100, a general purpose 100 MHz FT NMR intended to replace the aging HA-100.

Seeking to build on this foundation, Varian incorporated innovative technology in a spectrometer for routine ^{13}C work. We sensed that ^{13}C NMR would become popular with organic chemists only if it became easy. Needing a large sample and as high a field as practical for an instrument whose cost could not exceed the typical analytical laboratory budget, an electromagnet was chosen, operating at 20 MHz around 18.8 kG. A pulsed FT system, using a dedicated minicomputer (the Varian 620-i) and employing an internal lock based on the deuterium nuclei in the deuterated solvent was envisioned as the way to meet the sensitivity and stability requirements. Ease of operation was given a high priority in the design. That development was begun in 1969, and the CFT-20 became a mainstay in Varian's product line during the critical first half of the 1970s. Because of its advanced design, it could compete for some of the research funds in chemistry.

During the 1950s and most of the 1960s, Varian did a considerable amount of custom design to meet specific customer needs. Although high-resolution NMR finds its largest market with the organic chemist, spectrometers for studying ^{19}F , ^{31}P , ^{11}B , ^{15}N , ^{13}C , and others were developed and sold, as well as wideline instruments for studies of solids. The spin and magnetic moment of the unpaired electron led to the development of a commercial electron paramagnetic resonance (EPR) line of spectrometers. Separately sold laboratory magnets broadened the product offerings still more.

Competition had grown as companies sensed the opportunities in a burgeoning NMR market. During this same period, the business climate in the country was changing. Stock prices were influenced by analysts' expectations of earnings, and publicly owned companies like Varian found that a conservative management style was most appreciated. In addition, consolidation and diversification came into vogue in the mid-1960s. The theory being that the same sales force could sell a line of analytical products, Varian acquired in rapid succession Techtron in Australia, Wilkins-Aerograph and Cary Instruments in California, and Atlas-Werke, A.G. in Germany. Our instrument division, already spread thin with diverse NMR and EPR projects, also undertook the development of two mass spectrometers and an ESCA spectrometer.

The effect of those factors led to a shift in the allocation of research and development resources. With the deaths of Russell Varian in 1959 and Sigurd in 1961 the company had lost its two strongest champions of innovation. Thus, as the 1960s wound down, a paradoxical situation was developing. The company that had been responsible for the major breakthroughs of the decade turned its main attention to routine analytical instruments and gave only secondary attention to using its own breakthroughs to create state-of-the-art research spectrometers.

THE 1970S—THE TIME DOMAIN

The 1970s were truly the decade of the ascendancy of Fourier transformation in NMR. By the start of the decade, dedicated minicomputers able to carry out all processing and control functions had become available for use in NMR. Increases in speed and memory accompanied by plunging costs followed soon after and focused attention on the existing possibilities of digital data processing.

Although FT was invented in order to increase sensitivity, it offered other benefits that, within 10 years, made it the method of choice. Apparently incidental to the FT technique is the wideband pulsed excitation of all nuclei. Gradually, however, specialists in NMR research realized that pulsed excitation has value in its own right. After the pulse, the system is found in an excited quantum state. In the absence of external forces, it evolves under the influence of the interactions between the members of the spin system. At a later time, or with appropriate additional excitation, the system will be found in a state from which information about the interactions can be extracted. This general principle can be employed in an almost infinite variety of ways and may well be the greatest benefit of FT NMR.

Beginning with relaxation time measurements at the beginning of the 1970s, special pulse sequences proliferated for a myriad of purposes. Hahn's spin echo experiments from the early 1950s were recognized as a way to refocus chemical shifts and remove their defocusing effects. Coupled spin systems were shown to exhibit predictable redistribution of spin populations in their energy levels, leading to polarization-transfer experiments. Multiple quantum coherence, hard to visualize in vector form but a marvelously selective feature in a variety of experiments, was mathematically analyzed and applied. After Jeener's suggestions in 1971, a wide variety of two-dimensional NMR experiments were developed by Ernst, Freeman, Bax, and many others.

During the 1970s, however, such experiments could be used only by those who had programmable pulse generators, timing circuits, phase shifters, and phase detectors, and the know-how to operate such an array. In other words, time-dependent experiments were not user-friendly, so few chemists used them and the number of complex structure determinations made using the new techniques remained small. Most organic chemists had yet to accept ^{13}C NMR.

A huge task faced the instrument makers to make those powerful new experiments routine and educate the organic chemist in their application. Applying ^{13}C NMR requires a more thorough understanding of the subtleties of FT NMR than proton NMR. Relaxation behavior, spectral width, digital resolution, and quadrature detection were new concepts that had to be mastered. Furthermore, the chemical shifts of ^{13}C nuclei were not yet systematized. Assignments were particularly frustrating, since all the carbon peaks looked alike. But ^{13}C NMR added unique information that, in conjunction with the proton NMR data, could solve chemical structure problems more effectively and more elegantly.

We soon realized that the instrument for the support of organic chemists should be able to switch easily between acquiring proton or ^{13}C NMR spectra. The FT-80 evolved from the CFT-20 to meet this need and was further provided with a broadband synthesizer for multinuclear studies, a homonuclear decoupler, a microprobe accessory, and a second-generation minicomputer. Those improvements prolonged the product lifetime into the 1980s, and familiarized many chemists with the power of FT NMR.

In the Applab, during the first part of the 1970s, I was using an SC-300, a 300 MHz superconducting FT NMR spectrometer that had replaced the HR-220. I soon came to appreciate the value of the spectral dispersion and sensitivity of such a high-field strength. One unit was even pushed up to 360 MHz, providing more evidence of the advantages of higher field strength. But, because of overextended resources, the SC-300 had to be made to order by research and development engineers and technicians, which led to an unacceptable delay in delivery. Despite its excellence, the SC-300 had to be discontinued, and Varian set to work to design and engineer a replacement, the XL-200.

By 1978, when it was introduced, competing instruments were already available at 200, 250, 270, 300, 360, and 400 MHz. As far as leadership in research instruments was concerned, it was a case of too little, too late. But the XL-200 did meet the needs of the average NMR user better than its higher field competitors because of its innovative system for control and data acquisition. Two computers, one for each function, were connected by high speed data busses, and the entire operating program and work space resided on a hard disk. The software, written in PASCAL, made it possible for the operator to address the host computer directly through the keyboard. On command, the host computer would transfer the experiment parameters to a special acquisition computer that ran the experiment, averaged the data, and stored it on the disk. The XL-200, expandable and compatible with standard computer hardware, provided an ideal platform for future high-field instruments. During the late 1970s, Varian accumulated a vast body of software, which was easily transportable to new models with more powerful hardware.

Progress in FT NMR outpaced the ability of chemists to keep up. With new pulse sequences appearing in every issue

of the journals, we realized that many were just variations or specialized forms of standard sequences. The Applab tested promising sequences to define a set of 2D experiments with general applicability. Those were then included in the standard software, along with macro-commands to allow entire experiments from set-up to plotting to be performed by a few keyboard strokes. The results of this work were then communicated to the chemists by bulletins, lectures, workshops, and the chemical literature.

Two decades after the first instrument went to Baytown, Varian's R&D team and Applab represented a fraction of the talent focused on advancing the state of NMR technology. New developments in spin physics were appearing so fast that we could hardly keep up with them. A gradual shift in emphasis in research and development toward system design rather than component design took place, both in hardware and software. At the end of the 1970s, much had been learned about applying FT NMR to problems in chemistry. The time was ripe for a quantum leap in problem-solving power.

THE 1980S: NO PROBLEM IS TOO TOUGH

Even the sophisticated data system of the XL-200 could not overcome the limitations imposed by the slow speeds and small memories of the minicomputers of the 1970s. In the early 1980s, I could see the usefulness of the 2D NMR experiments but, unwilling to devote the time then required, I concentrated on using time-dependent experiments that could be done fairly easily.

To solve the problem that decoupling turned all ^{13}C signals into identical singlets, I used a pulse sequence that I had heard about that delayed acquisition for $1/(2J)$ s with the decoupler off. The precessing magnetization of the carbon is modulated differently for CH , CH_2 , and CH_3 groups. With $^1J(\text{C,H}) = 125\text{ Hz}$, an 8 ms delay gives positive CH_2 peaks, while CH and CH_3 peaks are negative. The decoupler is then turned on during acquisition. That gave the benefits of decoupling without the loss of information about the protons. We called this experiment APT, an acronym for attached proton test.

An even better experiment for that purpose soon appeared. Double quantum coherence is generated and allowed to evolve, followed by polarization transfer. Complete editing into CH , CH_2 , and CH_3 subspectra can be carried out with this DEPT sequence. Spectral assignments and interpretations were greatly facilitated with this pulse sequence.

In the meantime, the XL series of spectrometers had acquired two new members, the XL-300 in 1982 and the XL-400 the following year. The computer was upgraded and disk memory greatly expanded. Now I could apply the whole range of 2D experiments to chemical structure determinations. I was amazed at how consistently we could solve the most formidable problems, even with little beginning knowledge. (By the end of the decade when I retired, I had published a career total of 160 collaborative papers.)

The VXR line of NMR spectrometers, announced in 1985, was offered at 200, 300, 400, and 500 MHz. High-speed dual microprocessors far outperformed the earlier minicomputers, allowing all the 2D experiments to be performed with much larger data arrays which made the new instruments attractive to biochemists.

However, not all chemists had the funding to purchase a research grade instrument. The T-60 and FT-80 instruments were no longer cost-effective in comparison with superconducting instruments, so emphasis was given to the development of a powerful, user-friendly 200 MHz superconducting NMR spectrometer, priced to fit the organic chemist's budget. I was again involved in the design of a classic instrument. My assignment was to develop a menu-driven program that would demand no special skills to produce high quality proton and ^{13}C spectra. In August, 1986, the GEMINI-200 was announced, followed in 1987 by the GEMINI-300, and I became the Applab specialist providing on-going support for those products.

In 1987, deliveries from Oxford Instruments finally began for the 600 MHz magnets that had been announced in 1982. The VXR line of research NMR spectrometers was again upgraded in computing power and stability, and renamed UNITY. Varian had again begun to challenge the frontiers of NMR instrumentation technology.

THE 1990S AND BEYOND

The U-600 spectrometers currently in production have achieved 20-times the spectral dispersion of the original HR-30, an increase of 60 000 in sensitivity, several orders of magnitude improvement in stability, and a degree of user-friendliness that was unimaginable in the beginning. Progress in the early 1990s has accelerated although the directions have been changing. Magnetic field strength increased by a small increment (from 600 to 750 MHz) in 1993 but at a disproportionate increase in cost, suggesting that existing superconductors may be approaching a limit. Progress in spin physics has continued and inverse-detected experiments with various dimensionalities offer answers to the most formidable organic and biochemical structure problems. Pulsed field gradient experiments offer superior water suppression and a substitute for unwieldy phase cycling.

Improvement in computers continues unabated. Vastly increased speed and memory, combined with sharply falling costs, will certainly lead to new spectrometers of increased power and cost-effectiveness. Newer computers already incorporated in the spectrometers allow for much more sophisticated data-processing programs, such as linear prediction, multiparameter regression analysis, and molecular structure generation or modeling. Larger data sets can be handled quickly, giving improved resolution. The 1990s may turn out to be the decade of software.

The nature of breakthroughs precludes predicting them. One prediction can be made, however. I will not live to see the last breakthrough in NMR. Through a combination of rare opportunity and some perseverance, I have been privileged to participate in the early stages of a revolution that has succeeded beyond my wildest dreams.

Shulman, Robert G.: My Years in NMR

Robert G. Shulman

Yale University, New Haven, CT, USA

As a young naval officer at the end of World War II, I was in charge of maintaining radar aboard the USS Saratoga when it served as a troop transport and then as it was readied to be atom-bombed in the Bikini test. Radar had been installed late in the ship's life so that components were distributed throughout, with one particularly troublesome power supply seven decks down from our normal activity. Given certain symptoms, I had been told when taking over the responsibility, one hurriedly descended to that lower deck, dogging and undogging hatches, reached the power supply and kicked it soundly at a particular panel. Since this invariably fixed the radar and since the ship was heading for demolition, we never stopped kicking long enough to solve the recurring problem.

Two years later as a graduate student at Columbia, my advisor Charles Townes came into the laboratory where I was doing microwave spectroscopy using a superheterodyne spectrometer that had been built by Stan Geschwind, a fellow graduate student. It had developed a problem so I was walking around the equipment kicking different panels. Professor Townes walked in and asked what I was doing. 'Fixing it,' I said. He then started a line of questioning reminiscent of my year of training in radar maintenance, but which I had not thought of applying to a research problem. As he enquired about the transmitter output, the crystal detector and the like, I realized that a direction of rational experimentation was being described which could cure the uncertainties that haunted my laboratory hours. However, as my kicking illustrated, heavy duty instrumentation was not my strength. Still the attraction of experimental spectroscopy has remained with me as an understandable reliable methodology that, if working, enabled one to determine the properties of matter. Spectroscopy offered a means to reach the goals set to me as a Columbia College freshman by Professor Charles Beckman in a conversation—'We know the laws that describe the properties of electrons in atoms', he said, 'and we know how materials look, smell and react, but the problem is to describe the properties we can observe from the basic behavior of those particles we can't see.'

Several years later I was at Bell Laboratories in 1954 when John Mays, my friend from graduate school, was building an NMR spectrometer. I was by then engaged in semiconductor research and we thought it might be interesting to study In, Ga, and As in the novel III–V intermetallic semiconductors. We prepared powdered samples, saw the resonances, measured linewidths, calculated second moments, and found that the lines were too broad to be explained by dipole–dipole interactions. We were helped then and many times afterwards by Phil Anderson who had heard of a soon to be published theory by Ruderman and Kittel that calculated the exchange effects between nuclei mediated by conduction electrons. This was analogous to the J coupling previously developed for molecular bonds. The calculated exchange coupling from their theory depended upon the band structure

of these III–V compounds and we showed that a reasonable band structure agreed well with the NMR observation.¹ This experiment demonstrated how NMR could be useful in understanding electronic properties of semiconductors and by inference of other solids. For the next six years, with numerous young Bell Lab colleagues, I conducted NMR studies of semiconductors, superconductors, and condensed magnetic materials both paramagnetic and antiferromagnetic.

My own collaboration with John Mays continued on semiconductors until his interests turned to more chemical problems (1955). I was quite devoted to NMR investigations of solids by that time and had set up an independent NMR spectrometer with a Varian 12 in. electromagnet. I extended the semiconductor studies to Si, detecting the rather weak ^{29}Si signals and showing that relaxation times depend upon the conduction electron density. In the same issue of *Phys. Rev. Letters* (1956) that my ^{29}Si article appeared,² I published with Vince Jaccarino the first report of our NMR studies of magnetic solids starting with MnF_2 .³

Since I had been able to see a variety of nuclei in semiconductors, I thought that the ^{19}F resonance in MnF_2 was a promising reporter on the paramagnetic state of MnF_2 . We mounted a single crystal of MnF_2 and looked at the field satisfying the Larmor conditions without success. It wasn't until later, far downfield from the Larmor condition, that I saw the ^{19}F resonance. For the next five years I studied magnetically shifted resonances. At the time Jaccarino and I started, the literature on the effects of paramagnetic ions on nearby NMR signals was scanty. While Harden McConnell had shown that anisotropic dipolar interactions could produce the so-called 'pseudo-contact shifts', no one had seen shifts and explained them on the basis of hyperfine interactions from spins transferred to the ligand orbitals as we did in our first paper.

I was particularly interested in the chemical bonding information that these measurements could yield, and its consequences for the magnetic ordering. The shifts observed were explained in terms of bonding and antibonding molecular orbitals between Mn^{2+} and F^- . The antibonding orbital, containing the unpaired electron, had a wavefunction of the form $(\psi_{\text{Mn}} - \lambda\psi_{\text{F}})$. Orbitals of this form could be written for all the 2s and 2p atomic orbitals of six F^- ligands and all five unpaired 3d electrons of Mn^{2+} . The measurements revealed that the unpaired electrons, mainly and nominally Mn^{2+} 3d electrons, were really in antibonding molecular orbitals with a finite probability of being in F^- 2s and 2p orbitals whose coefficients λ were determined from the isotropic and anisotropic components of the ^{19}F shifts. These values were calculated by comparing the measured hyperfine interactions with those expected from a completely unpaired 2s or 2p electron.

In addition to the novel understanding of 'bonding' in previously considered 'ionic' crystals, the measured delocalization of the unpaired electron provided a quantitative basis of the 'superexchange' effect, proposed by Phil Anderson to couple nearby Mn^{2+} spins together in an antiferromagnetic. Put simply, it measured the probability of finding an unpaired spin from an Mn^{2+} neighbor in an F^- orbital. The polarity of this spin would affect the relative energies of up and down spins on a neighboring Mn^{2+} bonded to the same F^- and in this way the orientation of one Mn^{2+} was felt by its neighbor.

Amongst the many papers we published on antiferromagnetic solids, I only note that the cubic family of KMnF_3 , where M was an iron group ion, provided high symmetry sites that made NMR (and subsequent EXAFS measurements) particularly simple to interpret.⁴

Jaccarino and I succeeded in observing the ^{19}F NMR peak at ~ 170 MHz at 4.2 K in zero external field, in which this Larmor frequency was determined by the local field arising from hyperfine interactions with the antiferromagnetically ordered Mn^{2+} ions.⁵ Finally, I measured hyperfine shifts in solution complexes of FeF_6^{3-} and of H_2^{17}O bound to Gd^{3+} .^{6,7}

Among several other studies of solids by NMR during this time, I had the pleasure of collaborating with Berndt Matthias and Shlomo Alexander on NMR studies of intermetallic superconductors such as Sc_3In and NbMo .⁸ These gave Knight shifts in an unusual direction (upfield) which provoked a number of NMR studies of Berndt's exotic superconductors. Berndt was Swiss, a spiritual descendent of Paracelsus, and fascinated us all by his alchemist's power over matter.

I was invited to give a physics seminar at MIT on January 20, 1961 on magnetic materials. Before I visited my former CalTech room mate, Alex Rich, in the Biology Department, I watched John Kennedy's inspiring inaugural address on TV. Then Alex told me that some Russians had reported high concentrations of unpaired electron spins in DNA by electron spin resonance. He gave me some cotton-like threads of DNA which I took back to Bell Labs and persuaded W. M. Walsh to put them into his ESR spectrometer whereupon we saw a strong signal from unpaired electrons.⁹ That started a long path of research by ESR, fluorescence, and phosphorescence which I carried on with colleagues for about five years delineating the excited electronic states of DNA, the pathways of excitation transfer and of radiation damage, all of which is another story. The NMR consequence of this interest in biomolecules was that I spoke with Bill Blumberg and Terry Eisinger at Bell Labs who had built a pulsed NMR instrument designed to measure the increased H_2O relaxation they expected to find from free radicals generated during enzymatic reactions. By that time I had shown that the unpaired spins in DNA were from ferromagnetic magnetite inclusions, and I knew that the structure of paramagnetic metal ion binding to DNA was uncertain. If bound outside to the phosphates, the binding efficiency of Mn^{2+} should have been similar to the free ion, while if bound internally, the efficiency should have been reduced from limited H_2O access. We decided to test how the effectiveness of Mn^{2+} as a relaxation agent of the H_2O protons was changed by its binding to DNA. To our surprise, the Mn^{2+} was *more* effective when bound, a phenomenon which we named 'relaxation enhancement'. We explained it on the basis of the altered correlation time between Mn^{2+} and the H_2O protons which was determined by the rotation time of the $\text{Mn}(\text{H}_2\text{O})_6$ complex—a rotation time that would be slower when the Mn^{2+} was bound to the DNA molecule, making it more effective as a relaxer. We showed that Co^{2+} and Ni^{2+} , with very short electronic T_1 values, did not give this enhancement when bound to DNA, since the rotational time was shunted by the faster electronic relaxation. We published a note in *Nature* in 1961.¹⁰

That summer, Terry and I went to the Gordon Conference on NMR, where I presented these results. They were enthusiastically greeted by Mildred Cohn, amongst others, and we carefully explained to her the mechanism of relaxation

enhancement. It was at that meeting that Mildred Cohn, Oleg Jardetzky, Bill Phillips, Terry Eisinger, and I decided to hold a meeting on magnetic resonance in biology which convened two years later in Boston, and which held its 30th anniversary in the summer of 1994.

I had received a Guggenheim Fellowship to study solid state physics at Oxford, UK, and had received a year's sabbatical, with partial support from Bell Laboratories. However, my interest in the early part of 1962 had shifted to biological problems and Alex Rich had introduced me to Sidney Brenner, so that I received an invitation to work with Brenner and Crick in the academic year 1961–62 in Cambridge. It was my good fortune that both Bell Laboratories and the Guggenheim Foundation welcomed this change of plans and I am grateful to their high minded policies which enabled me to switch my interests to biophysics. In Crick's laboratory, I joined fascinating bacteriophage studies showing that the genetic code was read serially with frame shifts in the triplets following deletions or insertions. My contribution to this exciting project was to demonstrate the existence of chain-terminating triplets. It was published (or buried as Francis said) several years later in a long article in the *Philosophical Transactions of the Royal Society*.¹¹ I didn't learn very much biochemistry of the sort that would have been helpful during the next 10 years but I did learn, through participation, the excitement of front-line biological research. At the end of my stay I had to decide whether to continue in molecular biology or whether to return to Bell Labs and pursue the magnetic resonance studies of biological molecules I had been doing. I chose to return, in part because Sidney Brenner assured me that the heroic age of molecular biology had passed and in part because physical methods that I understood for studying materials were more advanced and available at Bell Laboratories than anywhere else.

While I was in England, Terry Eisinger and Bill Blumberg extended the relaxation enhancement studies. They had several conversations with Mildred Cohn, keeping her informed of developments which she could apply to her relaxation enhancement studies of Mn^{2+} bound to proteins which she had started at that time. She acknowledged our *Nature* paper and those informative discussions when she and Jack Leigh published their first paper in *Nature* in 1962, but soon afterwards became convinced she had independently discovered relaxation enhancement.

After the 1964 Boston meeting on magnetic resonance in biological systems, my NMR studies concentrated on paramagnetic metal ion binding to biological molecules. Himan Sternlicht came to work with me and with a new Varian XL-100 we looked at the effects of paramagnetic metal ions upon the relaxation times of the ^{31}P and ^1H resonances of ATP. We used the r^{-6} dependence of the relaxation rate to determine the structure of the M^{2+} -ATP complexes.¹² This was the first use of dipolar interactions to determine the structure of any compound and we presented these results at the 1964 Boston meeting. We explained the method to Al Mildvan, who subsequently used it to determine distances in numerous metalloenzymes. Once again we had the private satisfaction of seeing our NMR methods applied to enzymology by the group at the University of Pennsylvania. This work occupied our NMR spectrometer until the second meeting of the International Society of Magnetic Resonance in Biology (ISMRB) in Stockholm in 1966. There I was

electrified by the 220 MHz ^1H NMR spectra of the small proteins RNase and lysozyme presented by Bill Phillips. Suddenly the spectra showed well-resolved lines, particularly to higher and lower fields than the central resonances, but even in the overlapping region between 1 and 7 ppm sharp resonances could be observed. My previous experience at 100 MHz had led to the conclusion, which was widely if not universally held, that there were very few sharp lines in macromolecules, so that the well-resolved spectra at 220 MHz were very surprising.

I returned to Bell Laboratories and within a week had ordered a 220 MHz spectrometer which, when it arrived in early 1967, was only the second such installation in the world. At that time, Ian Smith was finishing his postdoctoral NMR studies of nucleic acids, particularly tRNA, at 100 MHz. For 220 MHz studies, Tets Yamane purified several milligrams of alanine tRNA, which after being concentrated for the ^1H NMR study, unexpectedly formed crystals. We had the crystals examined by the X-ray crystallographer who said they were rather soft crystals of an organic molecule. Since no one had crystals of tRNA at that time, it was a question as to whether I should redissolve the crystals and continue our NMR studies or retain them and become a crystallographer. After some thought, I told Tets to dissolve them. The small improvement in resolution of the ^1H NMR spectrum of the purified tRNA¹³ was very disappointing at the time and only recently have the NMR studies of nucleic acids rivaled X-ray crystallography as a source of information.

The next chapter in our tRNA studies came several years later, after we had been devoting most of our NMR time to the study of heme proteins. The heme protein study relevant to the tRNA saga came when Brian Sheard, a postdoc from Oxford, wanted to see if he could observe the exchangeable protons in Hb and Mb dissolved in H_2O rather than D_2O as was customary. He identified several histidine N–H protons which helped characterize the quaternary state of Hb.¹⁴ Soon afterwards, in 1969, Dinshaw Patel in my lab continued the studies of Mb and Hb in H_2O and used the exchangeable protons to follow the effects of ligand binding.¹⁵

In the fall of 1970, David Kearns came to spend about half of his sabbatical year with me to learn NMR with the determination to study tRNA by NMR. David and I had become friendly at meetings on the excited electronic states of biomolecules. I had looked forward to his visit although I warned him that our previous NMR studies of tRNA had not been very informative. When David arrived he continued to ask about tRNA possibilities until one day, thinking of Dinshaw's and Brian Sheard's studies of heme proteins in H_2O and of the observation by Penman and Katz of the hydrogen-bonded protons in the base pairs of Watson–Crick complementary bases when dissolved in aprotic solvents, I suggested that if he dissolved the tRNA in H_2O he would very probably see well-resolved resonances from hydrogen-bonded protons at very low fields. Since Dinshaw was actively studying H-bonded protons (he had by then moved to a permanent position in another department) we asked him to help with the experiment which he readily did. The experiment succeeded very well¹⁶ with unpurified tRNA giving low-field resonances (10–15 ppm) which subsequently were better resolved over the next six years.

Soon after returning to California, David involved his colleague Brian Reid at first because he could supply large

amounts of purified tRNA which gave beautiful spectra. However, very soon Brian, like David before him, became excited by NMR acquisitions and both became excellent spectroscopists, soon well instrumented, and pursued their ways separate from me and, soon after, from each other. In these tRNA studies, we used a computer of average transients and swept the field up toward the H_2O resonance which was not suppressed. Baseline correction became a highly developed subject. Resonances were resolved, quantitated, and assigned on the basis of AT pairs intrinsically being at lower fields than GC pairs, while ring current calculations of shifts were made from model structures to aid in assignments. Secondary structures were determined and partially successful efforts were made to identify tertiary structure hydrogen bonds.

One exciting aspect was the work done by Kees Hilbers, a Dutch postdoctoral fellow. In addition to structural studies (we had by then a 300 MHz Varian), he developed the kinetics of hydrogen-bond opening and proton-exchange rates with H_2O protons. In this we had the pleasure of collaborating with Don Crothers.¹⁷ At present, the H-bonded protons are not much better resolved than all the other protons because of powerful multidimensional NMR, and they make only a limited contribution to the structural information being sought. However, because of the unique sensitivity of their shifts to their bond strength and their direct dependence upon bond kinetics, I expect they will become more valuable in the future as NMR provides more functional information.

Although Maurice Gueron had left Bell Labs in 1967, after working with me on excited states of DNA he came several times as a summer visitor and it was on one of those visits in 1974 that his study of ^{31}P in tRNA gave information relating the ^{31}P chemical shifts to their immediate secondary structure, which also continues to be useful.¹⁸

My interests in the effects of paramagnetic ions upon NMR spectra continued throughout the 1960s. Gil Navon came and substituted Mn^{2+} for Zn^{2+} in carboxypeptidase which from dipole–dipole relaxation gave structural information about the active site. At the same time that we published a short paper on NMR studies of the structure of the active site of carboxypeptidase,¹⁹ Bill Lipscomb and his colleagues published the crystal structure. Their informative structure overwhelmed our limited information and turned me, prematurely (it subsequently developed), against using NMR to determine macromolecular structure. Fifteen years later when multidimensional NMR began to compete favorably with crystallography, I had long since left for *in vivo* studies.

When the 220 MHz spectrometer arrived in 1967, I had started to study heme proteins with Kurt Wüthrich who was a postdoc. A brief report had been published earlier by Arthur Kowalski about a downfield-shifted proton resonance in cytochrome *c*. I recognized this as a hyperfine shifted resonance and we started to study paramagnetic complexes of Mb, Hb, and cytochrome *c*, a reasonable direction since both Wüthrich and I had backgrounds in NMR paramagnetic shifts.

Our first studies resolved and identified the resonances from protons near the iron, particularly those on and near the heme ring.²⁰ We measured spin densities around the heme in the paramagnetic state which Martin Karplus, Si Glarum, and I later used to delineate the π -electron wavefunction.²¹ Numerous studies followed, including several in which the heme wavefunctions were used to calibrate the energy changes

of the iron–oxygen bond in the high and low affinity states. From this we showed that this bond's energy differed only negligibly in these two states compared with the differences of bonding affinity, so that the affinity differences had to be sought elsewhere in the molecule. We published this in *Science* under the provocative title 'The Absence of Heme–Heme Interactions in Hemoglobin'.²²

At this point, we were ready to tackle the question of the cooperative oxygenation of hemoglobin. Two theories existed then, as now. One, the Monod–Wyman–Changeux theory (MWC), assigned the increased affinity as more oxygen was bound to a molecular switch to a higher affinity quaternary state. The other theory, most recently presented by Dan Koshland, linked the affinity changes to ligand binding in which the number of ligands already bound (not the quaternary structure) determined the affinity. Because identification of the quaternary state had previously only been made in crystals which cracked during a quaternary state switch, it had not been possible to switch the quaternary state and to measure the affinity while keeping the number of ligands constant. Seiji Ogawa solved that problem (in my laboratory) by separating the four subunits of Hb into α and β chains and recombining them to form the mixed valency hybrids of $(\alpha^{\text{III}}\text{CN } \beta^{\text{II}}\text{O}_2)_2$ and $(\alpha^{\text{II}}\text{O}_2 \beta^{\text{III}}\text{CN})_2$. These could be deoxygenated to form the stable half-ligated tetramers. Under these conditions, the two quaternary states were close in energy so that by changing solution conditions it was possible to switch the quaternary state while keeping the number of ligands constant.

We monitored the quaternary state in solution by ^1H NMR since we had previously identified several resonances as quaternary state markers.²³ With the quaternary state identified, we then measured ligand binding kinetics by stopped-flow with Quentin Gibson, and showed that the affinity changed from high to low when the quaternary state was switched while the number of ligands remained constant.²⁴ This was the experiment that established the MWC model as a true description of hemoglobin cooperativity. John Hopfield, Seiji Ogawa, and I decided that if this model were correct it should be capable of describing the varied experiments on Hb involving kinetics, equilibrium binding, NMR, crystallography, pH dependence, spin-label EPR data, the role of allosteric effectors, etc. Accordingly we reviewed the literature going back 50 years and showed that the same set of three MWC parameters could satisfactorily explain all the data. We published this long review in the *Quarterly Reviews of Biophysics*.²⁵ When I presented the results in a lecture, I was told by an eminent British kineticist that this would not do because in this field 'Gentlemen do not reinterpret other gentlemen's data'. This comment was, in fact, quite encouraging, showing the need for this study which assumed a consistency in Nature.

Max Perutz came to accept the MWC model at about the same time and has written many descriptions of Hb function from this viewpoint. However, it was my contention at the time (1970) and subsequently that the proof that the affinity was determined by the quaternary structure and not the number of ligands came from Ogawa's hybrid experiments. Furthermore, after our numerous experiments showing that the affinity changes were not localized to the heme, John Hopfield generalized those findings to describe a delocalization of energy as responsible for its dependence on the quaternary state, which once again indicated that the discrete localized

changes that could be detected by crystallography were not responsible for the affinity differences. For a quarter of a century most of the scientific world has believed that X-ray crystallography has shown that the quaternary state is responsible for the energetic changes in affinity, but in fact this had been shown by the NMR studies. Furthermore, the NMR studies and Hopfield's theory show that the low resolution of X-ray crystallography cannot localize the bonds responsible for the energy changes.

At this time, I made a second major change in my research directions, turning from the study of macromolecules to metabolism in vivo. Looking back, both of these changes were stimulated by an attraction to the newer field and by a sense of having reached limits in the older field. In 1961, Sugano and I minimized the energy in an LCAO molecular orbital for KNiF_3 and obtained excellent agreement with the NMR-determined spin density, the optical, EPR, and magnetic properties of the complex.²⁶ The minimization done by a numerical calculation used atomic orbitals of Ni^{2+} and F^- because this ionic model obviously was a good first-order description and we were trying to calculate the perturbations from this ionic starting point. Despite the excellent agreement with all the experimental data, Arthur Freeman and Richard Watson made a similar perturbation calculation starting from a linear combination of Ni^{1+} and F^0 atomic orbitals with results that bore no relationship to the data. Since they claimed theirs was the correct perturbation treatment, the field was narrowed not to an understanding of the data but to the formulation of a numerical calculation, i.e. which set of atomic orbitals was the proper basis set—a field which Sugano pursued and resolved, but which did not inspire me to continue in the study of transition element complexes.

Similarly, 10 years later, when we showed that the energy of cooperativity in hemoglobin was diffuse, there seemed to be no way of describing the energies experimentally. The hopes that NMR and spectroscopy could evaluate the small energies of binding cooperativity and of catalysis had excited my Bell Labs group from 1962–72. We were inspired by Albert St. Gyorgi's messianic vision of quantum biology as the biology of the future, but the future was not arriving soon enough. My hopes of establishing a quantum mechanically based biochemistry were frustrated. My intellectual commitments and values were established by my years at Bell Labs studying condensed matter. The structure of solids was easily obtained by X-ray crystallography. It was not the structure but the electronic properties that presented a challenge and which explained the varied functions of solids, e.g. semiconductors, superconductors, and magnetic materials. Furthermore, our understanding of these electronic properties was advancing rapidly in the 1950s and 1960s by combined experimental and theoretical approaches.

The ability to understand the many-body problems posed by the electrons in solids provided a promising starting point for understanding biological complexities. This approach differed sharply from the more popular pathways scientists took into modern biochemistry and molecular biology which were inspired by the advances in macromolecular structure or in organic chemistry. At Bell Labs, in those times, quantum mechanical understanding of function seemed to have an unlimited future—a future that included biological functions as its greatest challenge. At the same time, the macromolecular structural information we had obtained from NMR was very

limited compared with the X-ray structures. Consequently, I welcomed the opportunity to follow metabolism *in vivo* in order to understand its control, since the control of *in vivo* fluxes seemed an achievable NMR goal. The control of *in vivo* fluxes represented an extreme reductionist goal, remote like a quantum explanation of biochemistry, but possibly achievable in a more immediate future. This goal has only recently been reached, as illustrated below in recent studies of glycolysis and gluconeogenesis. State-of-the-art structural determinations by NMR were achieved sooner. In accordance with my evaluation of 1974, quantum biology has progressed negligibly in this era of structural biology.

In 1974, my NMR studies of hemoglobin and tRNA were well established and becoming accepted in the biochemical community. George Robillard's NMR studies of chymotrypsin in my lab were giving information about the electron distribution in the charge relay system at the active sites of serine proteases.²⁷ In addition, that year I did the first EXAFS experiments on proteins at the Stanford Linear Accelerator with Peter Eisenberger. We started with rubredoxin, the simplest iron-sulfur protein and within a year had done the first studies on other iron-sulfur²⁸ proteins, several forms of hemoglobin and, with Gil Navon, carbonic anhydrase.²⁹ All of these studies still flourish 20 years later, and yet in that year, at the age of 50, I discontinued research directions which were finally flourishing after more than a decade of hard work. Why, after looking forward to the future, talking for years with my colleagues about how our work was creating a future molecular biophysics, why did I not continue moving smoothly into that future?

Partly, as I described above, I knew that the victory would be incomplete, that the dream of understanding biochemical function at a quantum mechanical level was still too far in the future. Part was that the challenge of creating a valuable role for NMR in biochemistry was satisfied. Part was that whereas we had been the largest and best equipped laboratory in the world doing NMR and spectroscopy of biochemicals, in 1974 other laboratories were overtaking us in size and equipment, since Bell Labs management, faced with divestiture, began to limit its commitment to NMR equipment. By contrast, the challenging possibility of understanding biochemical pathways *in vivo* seemed to be a realizable goal with existing equipment that would require a similar marshalling of my energies and intelligence. So that by changing fields I was maintaining the same inner life, where my efforts would strain in order to survive. By contrast I could have continued in NMR studies of biomolecules, although by then, in Sydney Brenner's earlier words it now was a field for 'grown-up boys'.

The early period of my *in vivo* NMR research started at Bell Labs and extended through my first three years at Yale, i.e. 1974–82. During this period, I used a 360 MHz vertical bore spectrometer to study cellular suspensions and perfused organs. The subsequent period of whole animal studies started in 1982 when Kevin Behar and Jan den Hollander succeeded in obtaining well-resolved ¹H NMR spectra from the rat brain at 360 MHz.³⁰ This was soon followed by the arrival of a 1.9-T 30-cm diameter horizontal magnet which facilitated animal studies and led to human studies in the third period.

These complex studies required expertise in biology, animal preparation, and in NMR physics. Fortunately, I have had a series of brilliant, helpful younger collaborators—Gil Navon, Seiji Ogawa, Kamil Ugurbil, Truman Brown, Jan den

Hollander, Hoby Hetherington, Rolf Gruetter, Wei Chen, and particularly Doug Rothman, who have generously shared their knowledge and energies with me.

Several recurring themes motivated the studies during this early period. First, bioenergetics and the Mitchell hypothesis, while gaining acceptance during those years on the basis of a limited number of experiments still lacked direct support. We used ³¹P NMR to measure the internal pH in tumor cells,³⁰ mitochondria,³¹ yeast,³² and *E. coli*,³³ and showed, in agreement with the hypothesis, that pH gradients were created when energized. In liver cells we were able to measure mitochondrial pH separately from the ³¹PO₄ resonances, cytosolic pH from the fructose-6-phosphate shift, and external pH with a pH meter.³⁴ In mitochondrial suspensions in a divalent metal-free medium, it was possible to separate internal and external ATP peaks as well as those from Pi. These mitochondrial experiments were followed by Seiji Ogawa after I left Bell Labs. My *E. coli* experiments were continued at Yale with Bob Macnab and his student, Anna Castle. We measured all the parameters needed to evaluate the Mitchell hypothesis in its original form as applied to the antiporter coupling between the Na⁺ and H⁺ free energy gradients across the plasma membrane of *E. coli*. We measured the Na⁺ gradient by ²³Na NMR and used paramagnetic shift reagents to separate internal and external Na⁺ concentrations. At the same time, the pH gradient was measured by ³¹P NMR and the membrane potential by membrane-soluble ionophores. The results showed that the Na⁺–H⁺ transporter maintained equilibrium between the ions over most of the range in support of Mitchell's hypothesis.³⁵ An interesting small electrogenic component was identified by Macnab which represented an extension of the first-order model.

While still at Bell Labs, Truman Brown and Kamil Ugurbil did the first *in vivo* saturation transfer experiments on the ATP = ADP + Pi reaction in *E. coli*.³⁶ Truman Brown then brought the saturation transfer method to Oxford to pursue the creatine kinase reaction in George Radda's laboratory, and this reaction has often been studied subsequently.

A second principal direction was the development of ¹³C NMR and ¹H NMR *in vivo* in order to measure concentrations of metabolites. Our first ¹³C experiments were done by Navon, Ogawa, den Hollander, Ugurbil, and Brown on suspensions of *E. coli*³⁷ and yeast³⁸ using 1-¹³C glucose as a label. While much of the same information could have been obtained from extracts, we were motivated by two reasons to develop the *in vivo* method. The first, which to my knowledge has never worked, planned to take advantage of the long *T*₁ values of ¹³C resonances so as to facilitate saturation-transfer measurements. The second, which has been very useful, developed label methods of measuring flux *in vivo*.

Sheila Cohen obtained beautiful spectra of ¹³C fluxes from labeled alanine, ethanol, and acetate in the perfused liver,³⁹ as well as in suspensions of hepatocytes.⁴⁰ These spectra have been the 'Gold Standard' for me, showing the kinds of informative, resolved spectra that could be obtained *in vivo*. Technical advances have recently made it possible to obtain spectra of this high quality from the human brain as discussed below.

A third principal direction was the study of the control of fluxes primarily by ¹³C NMR of labeled compounds. The ¹³C studies by den Hollander, Brown, Ugurbil, and Sharon Campbell-Burk⁴¹ elucidated the control of glycolysis in yeast

at phospho-fructose-kinase (PFK) which had been identified by numerous classical biochemical studies as 'the controlling enzyme'. From ^{13}C studies summarized elsewhere in these volumes, we concluded that PFK was not controlling the flux changes between different conditions but was being controlled by its substrate.⁴² Ten years later we showed that glycogen synthase (GSase), the enzyme reported to control the flux of glycogen synthesis in the muscle, behaved similarly to PFK—being controlled but not controlling.⁴³ Both of these findings depended upon the novel measurements afforded by *in vivo* NMR.

Finally, in this period, Jacqueline Barton conducted a series of experiments on yeast spores for which, in the culminating paper with Jan den Hollander and John Hopfield,⁴⁴ we showed that during dormancy the ATP level was controlled at a low level (0.2 mM) and maintained there by ATP feedback control of the enzyme trehalase. This change in state came from changes at the somatic level induced by changes in the nutrient supply. In the many papers trying and failing to explain this development by changing gene expression, no attention has been paid to this simple explanation of the change from a growing state to a dormant one.

Since 1986, when we installed horizontal animal and human magnets at the Yale Medical School, I have been concentrating on muscle, liver, and brain research in humans and animals. In the muscle and liver, we have mainly studied glycogen metabolism. This approach started in 1983 when Laurel Sillerud showed that the ^{13}C resonances of glycogen were well resolved and 100% visible despite its high molecular weight.⁴⁵ Subsequently, we showed that the ^{13}C glycogen resonances in the muscle⁴⁶ and liver⁴⁷ *in vivo* are 100% visible and provide a sensitive, noninvasive means of measuring glycogen concentrations and rates of synthesis. Our human glycogen studies started in collaboration with Ralph De Fronzo, who expected that during a hyperglycemic–hyperinsulinemic clamp simulating postprandial conditions, most of the glucose being stored would be used to synthesize muscle glycogen. By measuring the rate of muscle glycogen synthesis with ^{13}C NMR and comparing it with the rate of glucose consumption, we showed that ~80% of the glucose was converted to muscle glycogen, the small remainder being used for energy and for liver glycogen synthesis. Comparison of the normals with noninsulin-dependent diabetes mellitus (NIDDM) patients showed similar glucose disposal in the patients, but the rate of the muscle glycogen synthesis was reduced ~50%.⁴⁸ This reduced rate was responsible for their slow glucose absorption, their major symptom. To locate the defect in the muscle glycogen synthesis pathway, we managed to resolve the ^{31}P resonance of glucose-6-phosphate (G6P) so that its concentration could be measured *in vivo*. Under identical clamp conditions the G6P was less concentrated in the NIDDMs, showing that the defect was before the G6P in the glucose transport/hexokinase region. The next study was made of prediabetics, children of diabetic parents who had not yet shown the disease. They were studied to test whether the reduced transporter/hexokinase activity noted in the NIDDMs had been induced or 'down regulated' by chronic hyperglycemia. The prediabetics were similar to the NIDDMs, i.e. under the same clamp conditions they had a much slower rate of glycogen synthesis and a lower concentration of G6P than their controls, showing that the transport defect was indigenous.⁴⁹

These NIDDM studies have been complemented by experiments measuring the rate of glycogen synthesis in normals after they have performed intense glycogen-depleting exercise of a muscle.⁵⁰ These experiments have shown that immediately after intense exercise there is a rapid glycogen resynthesis and that this rate is insulin independent in contrast to the slower, insulin-dependent rate of glycogen synthesis observed as the glycogen levels approach normal. The insulin-independent rate of glycogen synthesis has clinical consequences for the control of diabetes, suggesting that intense glycogen-depleting exercise would help diabetics. These glycogen experiments illustrate how a definite result of a basic research program, i.e. the visibility of the glycogen ^{13}C NMR, can be developed to the point where *in vivo* NMR experiments can delineate the control of its synthesis. This allowed us to determine the nature of a serious illness and these studies suggested a means of controlling the disease.

The ^{13}C NMR studies extending over a decade revealed the control of glycolysis in yeast and of glycogen synthesis in muscle. They have finally realized my 1974 hopes that *in vivo* NMR studies of metabolism can conceptually advance biochemistry. This has been done in the following way. Although the first experiments measuring the flux of glycogen resynthesis after exercise were performed on the human gastrocnemius, the more detailed biochemical understanding has come from subsequent rat studies.⁵¹ In those, Gilles Bloch showed quantitatively that the flux through glycogen synthase (GSase) was controlled by glucose-6-phosphate fed forward from the glucose transporters. The conclusion was that muscle glycogen synthesis during repletion from intense exercise was controlled by glucose transporter activity. GSase activity was regulated so as to accommodate the controlled flux, but it contributed negligibly to the flux control. This noncontrolling role for GSase, the prototypical site of flux control by covalent modifications, has widespread consequences for modern biochemistry and molecular biology where phosphorylation of an enzyme is considered definite proof of control. These studies show that while phosphorylation and flux control play a role during the control process, it is (in GSase) an indication that the flux is being controlled, not a cause of that control.

The study of brain activity has been underway in my laboratory since 1981. Kevin Behar, my first graduate student, said he wanted to do his research on *in vivo* NMR under my direction. When I asked what he wanted to study he said 'the brain'. From the beginning of the brain studies I have wanted to use *in vivo* NMR to understand the control of glucose metabolism, as we did in yeast, and to achieve the highly resolved spectra we had seen in our ^{13}C studies of microorganisms and perfused liver. These goals have been steadily approached while we have, as opportunities arose, been able to supplement them with additional goals. The major direction of using ^{13}C as an isotopic label, which we had been doing in the early Bell Labs studies, was extended in the brain to heteronuclear editing in which we followed the ^{13}C label by ^1H NMR through the resonances of its *J*-coupled protons. One of the first experiments I did at Yale compared the ^1H spectrum in yeast which had been fed 1- ^{13}C glucose, with and without ^{13}C decoupling. This primitive experiment was brilliantly extended by Doug Rothman to the rat brain by a heteronuclear editing method which, with minor improvements, still remains 10 years later the best method for following brain glucose metabolism.⁵²

We demonstrated the editing method first on the rat and measured the flow of ^{13}C from 1- ^{13}C glucose to C_4 of glutamate.⁵³ We established a simplified robust model for converting the measured rate of glutamate turnover into the Krebs cycle rate.⁵⁴ The measured Krebs cycle flux would determine both the cerebral metabolic rates of oxygen (CMRO_2) and glucose (CMR glucose) during normal oxidative glycolysis. PET experiments by Fox and Raichle in 1988 suggested that during visual stimulation the value of CMR glucose increased appreciably in the visual cortex while CMRO_2 remained constant. If these rates were truly uncoupled, then our measurement of Krebs cycle activity would reflect CMRO_2 but not CMR glucose since glucose was presumably not metabolized past lactate. In response to this need, Wei Chen developed an independent method for measuring changes in CMR glucose during visual stimulation which gave values in agreement with the PET results.⁵⁵ That leaves the challenge of measuring changes in CMRO_2 by the glutamate turnover method in the visual cortex during photic stimulation—a study which is underway.

In several recent studies we localize the activated region by functional MRI in which, as originally proposed by Seiji Ogawa, one measures the image differences with and without stimulation.⁵⁶ He expected that differences in the H_2O resonances forming the image would appear because of changes in the concentration of the paramagnetic deoxygenated hemoglobin—a proposal which clearly goes back to his extensive studies of hemoglobin. The functional MRI method has great sensitivity and resolution in following brain activation both during sensory stimulation⁵⁶ and during more complex cognitive tasks.^{57,58}

With the great promise of these imaging and spectroscopic studies of the human brain, which bring NMR to the forefront of brain research, I feel that the heroic age of in vivo NMR is reaching its conclusion, just as Sidney Brenner, 30 years ago, advised me that the heroic age of molecular biology had passed. In vivo NMR is now assured of a successful future. As such it may no longer provide the despairing challenge that drove us in the early years.

I have gone from NMR studies of a variety of solids with important electronic properties to biological molecules, to in vivo metabolism, and recently to the localization and energetics of brain function. While I cannot, like the Mongol conquerors, claim never to have slept twice in the same place, I can claim to have steadily broadened the scope of my attempts to explain Nature in atomic terms, and NMR methods have been my sword and shield.

Biographical Sketch

Robert G. Shulman b 1924. A.B., 1943, Ph.D., 1949, Chemistry, Columbia University, USA. Postdoctoral work at Caltech. Head of biophysics research, Bell Telephone Laboratories, Professor of Molecular Biophysics, Biochemistry, and Chemistry, Yale University, 1979–present. Approx. 400 publications. Current research specialties: in vivo NMR spectroscopy and functional imaging of brain, spectroscopy of liver and muscle.

Slichter, Charles P.: Early Days of Magnetic Resonance Studies of Solids

Charles P. Slichter

University of Illinois, Urbana, IL, USA

In this article, I describe some of the work in which I took part in the early years of magnetic resonance—the time interval 1947–57.

GRADUATE SCHOOL DAYS

My undergraduate study was interrupted by World War II. With the help of my adviser, J. H. Van Vleck, I was hired by the noted Harvard chemist E. Bright Wilson, Jr. at the end of my sophomore year (1943) to work on a war project at the Woods Hole Oceanographic Institution. My duties were to design, build, operate, and repair electronic circuits.

I returned to Harvard in January 1946, and graduated at the end of the summer school. In the fall I began graduate study in physics at Harvard. That winter Professor Van Vleck stopped me in the hallway one day to suggest that I ask Professor Purcell if I could do a thesis with him studying electron spin resonance of paramagnetic salts. I did not know who Professor Purcell was, what electron spin resonance was, nor why paramagnetic salts were of interest. However, I knew Van, as everyone called him, and acted on his advice. His advice was indeed wise, and I will forever be grateful for it because happily for me Purcell agreed to take me on.

At that time Nico Bloembergen, Purcell's first student, was just finishing his thesis research. George Pake (Purcell's second student) was in the midst of his work, and I became Purcell's third student. Bob Pound, a so-called Junior Fellow at Harvard, was working on quadrupole effects in NMR right across the hall from Purcell's laboratories. In my last year, Raymond Andrew came as a Commonwealth Fund Fellow.

I was the only one working on electron spin resonance. Purcell, Pake, and Pound who had all had microwave experience gave me help in designing a microwave cavity and with other aspects of microwaves. I put together a 3-cm microwave spectrometer with a magic tee bridge using surplus microwave parts we got from the Radio Research Laboratory, Harvard's radar countermeasures laboratory. Copying at microwaves the NMR methods, I ran the bridge off-balance but with the cavity tuned to resonance to make the signal proportional to χ'' .

My thesis consisted of two parts, measurements of some crystal splittings in some paramagnetic salts using a frequency-stabilized klystron, and the measurement of the electron spin–lattice relaxation time in those salts by studying the saturation of the ESR (using a pulsed magnetron to generate large microwave fields). Although both experiments were pioneering in technique, I foolishly never published the results.

One day, while examining the effect of a magnetic field on the electronic energy levels of an Fe^{3+} ion, I noted that when the electron spin Zeeman energy is about two-thirds

of the zero-field crystal splitting, the electron spin $M = -\frac{1}{2}$ and $M = -\frac{3}{2}$ states cross. Reasoning that one should be able to observe the crossing with an NMR rig, which is at a much lower frequency than microwaves, I borrowed George Pake's NMR apparatus to search for this effect. Unfortunately I was unsuccessful, perhaps because the crystal splittings were much smaller than we originally expected. However this failed experiment was very important to me since, as I describe below, it later made me think of doing resonances at nonconventional frequencies and fields, such as electron spin resonances using a nuclear resonance apparatus, searching for the Overhauser effect at static fields of 30 G, measuring conduction electron spin susceptibilities by comparing them to nuclear susceptibilities, and measuring nuclear relaxation times in superconductors by cycling the static magnetic field.

My main interest has always been trying to solve important problems in physics and chemistry by resonance methods, rather than primarily to develop resonance techniques. However, I have wanted to invent new resonance methods when appropriate to solve a given scientific problem.

THE STUDY OF SOLIDS BY MAGNETIC RESONANCE

While I was a graduate student, Pake discovered the famous Pake doublet from water molecules in gypsum. Then, he and Herb Gutowsky (who was doing his Ph.D. thesis with Professor George Kistiakowsky) extended this work to a variety of hydrocarbons containing coupled pairs, triples, and quadruples of protons. They observed static splittings and line narrowing due to molecular motion in the solid state. This work, together with the work of Bloembergen, Purcell, and Pound on relaxation in liquids, led me to believe that magnetic resonance would be a powerful method for studying solids. The recent discovery of the transistor had made everyone aware that solid state physics would be an important area of physics, and the book 'Modern Theory of Solids' by Fred Seitz served to define the existence of such a field. Although I had not taken a course in solid state physics, I knew this book.

I was therefore quite excited when in my final year of graduate work (1949) I was invited to join the Physics Department of the University of Illinois, where Fred Seitz was about to go (from Carnegie Tech) with a small group to start a program in solid state physics. The chance to learn from Seitz and the group he was assembling seemed ideal. I was correct. The interaction with my colleagues at Illinois and also with Herb Gutowsky (and later Harry Drickamer) in chemistry were crucial sources of ideas for what problems to tackle.

When I got to Illinois, there was already a small group working in NMR. Erwin Hahn had just finished his Ph.D. (June 1949), studying the response of proton spins to pulses, and that summer had discovered spin echoes and had developed an explanation of how the echo arose using the Bloch equations. The year we were together prior to his departure for Stanford was truly wonderful for me. Dick Norberg and Ed McNeil were graduate students planning to work in NMR. Hahn, Norberg, and McNeil were all married, but I was 25 years old, single, living in the laboratory morning, noon, and night, and two young theorists, Sid Drell and John Blair, who were also single, became my constant companions and warm friends.

My original idea was to set up an ESR rig and to look for the signal from F-centers. There was no microwave apparatus, but

I intended to order parts to build a microwave superheterodyne. However, I then learned that Beringer and Castle at Yale, using a sensitive bolometer rig, had looked without success for an ESR signal from F-centers, and thus decided instead to start initially with NMR.

In Purcell's group, everyone was doing steady-state experiments. I had not studied Bloch's papers since I was so involved in mastering microwave methods, steady-state magnetic resonance, crystal field theory, and the concept of the famous BPP (Bloembergen, Purcell, Pound) paper. Every calculation we did was quantum mechanical. Erwin taught me the Bloch equations and the beauty and utility of the classical description (especially when considering transient effects). The transformation in my viewpoint (the necessity of understanding both classical and quantum mechanical descriptions) permeates the spirit of the second chapter of the textbook I later wrote.

I made no contribution to understanding why echoes arose. Erwin had already done that. However, when Erwin discovered that diffusion in a magnetic field gradient shortened T_2 , I was stimulated to develop a rigorous theory of the effect as Erwin kindly mentions in his article in this Encyclopedia (see *Hahn, Erwin L.: Pulsed NMR—A Personal History*). The calculation of the effect of diffusion on T_2 is given in a footnote in Erwin's famous spin echo paper. I think neither of us realized that this method would be used for studies of diffusion in liquids. If we had, perhaps we might have written a separate paper on the topic.

Dick Norberg was officially working with Professor Bartlett, but I became his unofficial advisor since Professor Bartlett was not an expert in magnetic resonance. Though Bartlett never worked on magnetic resonance, he was a theorist with enormously broad interests. Aware of Bloch's work on nuclear induction, it was Bartlett who originally suggested the field to Hahn for this thesis. Dick, enrolled in Professor Seitz's course in solid state physics, was excited by the lecture on what happened when hydrogen was adsorbed by Pd. Dick came to me to suggest studying that system by proton NMR. In the course of these studies, Dick used spin echoes to study T_1 and T_2 . This was the first use of pulsed NMR to study solids.

Herb Gutowsky, who had joined the Illinois Chemistry Department in 1948 on completion of his Ph.D., had decided that NMR would be a powerful tool in chemistry. Though he had no background in electronics, he assembled a steady-state NMR rig in the Chemistry Department with the help of an electrical engineering undergraduate and embarked on a variety of NMR studies. His decision to undertake this work was an act of great insight as well as courage. Remember, there were no commercial rigs. They only came along after Herb and others proved how important NMR was for chemists.

In one of his studies, Herb observed that in solid Na metal the NMR line began to narrow at about 160 K, continuing the narrowing until 220 K. Above that temperature he could no longer measure the intrinsic linewidth since the linewidth was limited by magnet inhomogeneity. Since the melting point of Na is about 380 K, Gutowsky recognized that the narrowing arose from diffusion in the solid. Realizing that spin echoes eliminated the effects of magnet inhomogeneity on the T_2 , Dick and I saw an opportunity for pulse techniques to extend the motional narrowing effects to much higher temperatures. The joint paper we published on our results was my first scientific publication.¹ Dick and my student Don Holcomb

then extended these studies to ^7Li and ^6Li , as well as ^{85}Rb and ^{87}Rb .

Another important first in pulsed NMR took place in our laboratory in spite of me. Myer Bloom, a young Canadian graduate student from McGill University, had joined the group. One day he came to me to propose that it should be possible to produce spin echoes in pure quadrupole resonance. He proceeded to do a long calculation (10 or more pages as I recall) to verify the theory. Meanwhile, I developed a simple symmetry argument which convinced me echoes would not form. He asked me to check his calculations, but I realized that a simple sign error could cause his answer to be nonzero rather than zero. I suggested that he find my error. Dick Norberg (who by then was a postdoc) had built a pulsed rig running at about 30 MHz. Instead of tracking down my error, Myer and Dick (without telling me) set out to observe quadrupole echoes of Cl nuclei. One morning when I arrived at work, I found a scope photo of Myer's quadrupole echo on my desk!

MY INTRODUCTION TO CHEMISTRY

My contact with Herb was natural, since we'd known each other quite well at Harvard. But it was further enhanced by the fact that none of the theorists in the Chemistry Department at Illinois at that time did quantum mechanical calculations. Relative to them, Herb seemed to classify me as a theorist. This attitude led to an interaction which was enormously stimulating, educational, and satisfying to me.

I have already mentioned how our interaction led to my interest in the diffusion in Na. Another conversation with Herb led to the first real effort to understand the relationship of chemical shifts to chemical bonding. It arose from the discovery by Gutowsky and Hoffman² of the systematics of F chemical shifts as a function of the electronegativity of the atom bonded to the F. In particular, the most covalent compound, the F_2 molecule, had a paramagnetic shift of 6.3×10^{-4} relative to the most ionic bond in HF. These shifts were enormous compared with the shifts of protons ($\sim 3 \times 10^{-5}$). At that time, Ramsey had developed a general theory of chemical shifts, primarily because of his involvement with molecular beams, and had applied it to the hydrogen molecule. It showed that shifts arose from the orbital motion of electrons. There were two terms, labeled diamagnetic and paramagnetic by Ramsey, but he pointed out that a change in gauge changed the size of the individual terms (though not their sum). Feeling that the most important contributions came from the valence electrons of the atom containing the nucleus under study, I noted that for fluorine these were p electrons. They thus possessed orbital angular momentum which, however, was quenched by the chemical bonds. However, if the applied magnetic field partially unquenched the orbital angular momentum, a large shift should result. This mechanism was not available for s states, hence the large difference in shifts between F and H. One could easily pick out this contribution by proper choice of gauge. I enlisted Herb's student, Apollo Saika, in carrying out the detailed calculations and numerical estimates.³

A third interaction with Herb arose when he and his student Dave McCall discovered that both the ^{31}P and ^{19}F resonances in liquid POCl_2F , POClF_2 , and CH_3OPF_3 were split into several narrow lines. By counting lines, one could see that the

splittings arose from coupling of the ^{31}P nuclear spins with the ^{19}F spins (the ^{31}P resonance in POCl_2F consisted of two lines, that in POClF_2 consisted of three). Since these were liquids, one expected the direct dipolar coupling to be averaged to zero as in the ^1H resonance of water. We discussed some of the proposed explanations (rotational hindrance, second-order dipolar interaction), and found that they could be eliminated. We concluded that the spin–spin coupling must be indirect, going via a polarization of the electron system. The spectra could be understood if the coupling were proportional to $M_{\text{ZA}}M_{\text{ZB}}$, where M_{ZA} (M_{ZB}) is the component of the nuclear moment $\mathbf{A}$ ($\mathbf{B}$) along the static field (z direction). Originally, I thought the mechanism must be via the electron orbital moments, as in chemical shifts, because the splittings in PF_3 were 10-times bigger than those in PH_3 . Such a process in a liquid would give a coupling of the form $\mathbf{M}_{\text{A}} \cdot \mathbf{M}_{\text{B}}$ between nuclei $\mathbf{A}$ and $\mathbf{B}$. At that time, Erwin was at Stanford, where he was trying to understand a mysterious modulation of the echo envelope of ^1H spectra in various molecules (which he had actually discovered in spectra at Illinois). We called it the ‘slow beat’. He also speculated that it arose from a coupling (in this case between chemically nonequivalent ^1H atoms in a molecule). Gutowsky suggested that we use echoes to look for a slow beat in BrF_5 in which he and McCall had seen splittings in their steady-state spectra. My student Ed McNeil studied the spin echoes of this material and showed that it had indeed a slow beat, and that the slow beat frequency corresponded to the spin–spin splitting seen by McCall and Gutowsky.⁴ Thus we knew that Erwin and we were studying the same phenomenon.

One of the chief mysteries was that in a molecule like BrF_5 , in which there are two chemically shifted groups of ^{19}F nuclei, one group containing four atoms, the other a single F, the group of four split the resonance of the single F and it split the resonance of four, but there were no splittings attributable to couplings among the four. Erwin told us that he had done a calculation that showed that for two coupled spins with different chemical shifts, an interaction like $\mathbf{M}_{\text{A}} \cdot \mathbf{M}_{\text{B}}$ had the desirable feature of giving no splittings when the chemical shift difference vanished. Stimulated by this remark, I succeeded in generalizing the result for larger groups of spins, and for both steady-state and pulse experiments, thereby explaining the absence of splittings arising from couplings within a chemically shifted species.

One of the important facts discovered by McCall and Gutowsky was that we never saw splittings from nuclei whose spins were greater than $\frac{1}{2}$. We decided this must be because they had rapid spin–lattice relaxation times, which flipped their spins so rapidly that they did not maintain their orientation long enough to produce a splitting.

When we were first thinking of some indirect coupling process, I realized it must involve some sort of anisotropic polarizability since the resultant coupling must not average out over the molecular tumbling. I already understood the F chemical shifts including their anisotropy and that influenced me to think that nuclear moment–electron orbital moment coupling, taken to second order, was the most likely candidate. That would explain why the coupling in PF_3 was so much stronger than in PH_3 . However, Ramsey and Purcell came up with a mechanism which gave even stronger coupling, based on interaction between the nuclear moments and the electron spin magnetic moments of electrons in bonds. I well remember my feeling of chagrin, when I learned of their mechanism,

that I hadn’t thought of the electron spins and that I had let Herb and Dave down. In an article on chemical shifts which I had read earlier, Ramsey had pointed out that spins would not contribute to chemical shifts. I had accepted this argument readily since I knew there was no net electron spin in our molecules. But of course, there was no net orbital magnetism either in the absence of an applied field. The question I should have asked was whether or not an applied field could induce a spin polarization. The answer is that a *nonuniform* magnetic field, such as a nucleus produces, can, whereas a uniform field from the magnet cannot.

In a similar way, rapid chemical exchange involving the OH group could explain why in $\text{CH}_3\text{CH}_2\text{OH}$ there were splittings induced between the CH_3 and CH_2 protons, but neither show splittings from the OH. I decided to model this phenomenon by setting up a pair of Bloch equations to describe a nucleus which could precess at either of two frequencies, and that jumped randomly in time between the two frequencies. When I solved the problem, I found that I had a formula to describe how a pair of lines would broaden, turn into three lines, finally collapsing to a single line as the mean time between frequency jumps got progressively shorter. When I showed the result to Herb, he suggested that we include it in the paper we were writing on the multiplets even though we had no experimental confirmation of the equations.⁵

Subsequently, Herb and Apollo Saika and then later others of Herb’s students applied the equations (and subsequent generalizations) to study chemical reaction rates in a notable series of papers.

CONDUCTION ELECTRON RESONANCE

In the fall of 1951, Al Overhauser came to the University of Illinois as a postdoc. For his Ph.D. thesis at Berkeley he had calculated the spin–lattice relaxation time, T_1 , of conduction electrons in metals. During the course of his calculations, he had discovered that if one saturated the conduction electron spin resonance, the nuclear spin polarization would be increased by the ratio γ_e/γ_n where γ_e and γ_n are the electron spin and nuclear spin gyromagnetic ratios, respectively. He urged us to look for the effect.

At that time, no one had observed the conduction electron spin resonance, but his estimate of the T_1 value was so long (about $1\ \mu\text{s}$) that the actual electron spin resonance would be only about 0.06 G wide, and thus should be very intense even though only those electrons in the tail of the Fermi distributions would be permitted by the exclusion principle to take part. One might wonder then why the resonance had not already been seen from electrons in the copper walls of the microwave cavities used for studies of paramagnetic salts. Purcell had proposed an explanation when I was a graduate student. He had pointed out to me that the conduction electron ESR line would have been very broad since electrons moving with the Fermi velocity would spend such a short time within the microwave skin depth of the metal surface. At radiofrequencies, however, we were routinely studying NMR in metal powders in which the individual particles of metal were smaller than the skin depth. At this point, I remembered my unsuccessful experiment with George Pake’s NMR rig to detect a level crossing on an electron spin system. Why not look for the predicted narrow ESR line with an NMR rig, thereby eliminating skin depth

problems? I wound a solenoid with end-correction windings to produce a very uniform static field, and my student Don Holcomb and I looked with a steady-state NMR apparatus. Though we investigated Cu, Ag, Al, and even a sample of Na, we had no luck. Finally we gave up. Then, one morning in the fall of 1952 a new issue of the *Physical Review* came, containing the famous article by Griswold, Kip, and Kittel reporting observation of the conduction electron resonance in Na. I rushed up to the lab. No one was there (it was lunchtime). I took the sample of Li metal whose NMR Don Holcomb and Dick Norberg were studying, put it into the coil of a transitron NMR circuit which we had built to monitor the static field strength of our magnets, put the coil into the solenoid, connected the solenoid to a Variac to sweep the field of the solenoid, and displayed the output of the transitron on an oscilloscope. Lo and behold, there was the conduction electron spin resonance of lithium metal! The signal was enormous, even at about 30 MHz (20 G), with a width of 5 G, but it was also very much broader than we'd expected.

We quickly checked Na, finding also a broad (10 G width) but strong resonance. Tom Carver and I immediately set to work on the Overhauser effect. Al had suggested several methods of detecting the nuclear polarization effects, but Tom and I felt the best approach would be a direct observation of the population enhancement of the metal nuclei by measuring the increase in intensity of the metal NMR produced by saturating the conduction electron spin resonance (CESR). That is, we proposed to do a double resonance experiment in which we monitored the effect on the NMR intensity of saturating the CESR.

We first proved that the source of the width of the CESR was spin-lattice relaxation by studying the saturation of the CESR in a static field of about 10 G. The broad line breadths meant that we needed a strong rf field (5–10 G) to saturate the CESR.

The most difficult design question was selecting the strength of the static field (H_0) at which to do the double resonance. From the NMR viewpoint, a strong H_0 was important. At 10 G, the ^7Li NMR is at a mere 16 kHz. At that frequency, there was no chance of seeing the normal ^7Li NMR, but perhaps one could detect the signal if it were enhanced 1000-fold by the Overhauser effect. On the other hand at 3 kG the NMR would be directly observable in a bulk sample, but the CESR would be at the 3 cm microwave band. I knew from my thesis that no power sources available could produce a steady-state saturation of the CESR (a pulsed magnetron would be necessary). Moreover, saturating the CESR would require sample dimensions which kept the electrons within the rf field, i.e. a sample thickness less than the microwave skin depth. Such a thin sample would then lead to a much weaker NMR signal.

We settled on a low static field. We first built an NMR rig to operate at 25 kHz. The bridge element was a brand new design we had not used before. We had no commercial power amplifiers in the 10's of MHz region needed for CESR, so we built a high-power push-pull oscillator following the 'Radio Amateurs Handbook' for the techniques needed for the 100 MHz region. We likewise had no frequency measuring equipment for the CESR oscillator, so we built a parallel wire transmission line arrangement to measure the standing wave pattern to determine the wavelength of the oscillations.

Our first efforts at 25 kHz NMR frequency were unsuccessful, so we tried working at 50 kHz. We still failed to see an NMR signal. We tried to test our apparatus by looking for the proton resonance of glycerin, still with no success. Then we built a 50 kHz preamplifier, followed by a mixer which transformed the signal to 500 kHz which we fed into a communications receiver. With this arrangement we succeeded in seeing the protons in glycerin. Changing the NMR coil (the glycerin sample was much bigger than the Li sample), Tom Carver tuned up the CESR oscillator, then turned it off to balance the NMR bridge. I was across the lab from him when I heard him shout with glee. When he had turned the CESR oscillator back on (thrown the plate voltage switch) a giant NMR line popped up on the scope. There it was—the Overhauser enhancement! Though we could not detect the unenhanced ^7Li NMR line at 50 kHz, we quickly checked the enhancement by comparing the enhanced ^7Li signal with the glycerin proton signal.⁶

From the time we learned of the success of Griswold, Kip, and Kittel (late November 1952) until our success (July 1953) about nine months had elapsed. We were elated. At the meeting of the American Physical Society, in Washington, DC in April 1953, Overhauser had first described his polarization scheme to the world in a 10 min talk. A large crowd of the most famous people in magnetic resonance were in attendance, drawn by the abstract. They were skeptical of his prediction, feeling that it somehow violated the second law of thermodynamics. Overhauser had announced that Tom and I were trying to test his prediction. Overhauser had to leave quickly after his talk and so the crowd, containing several famous scientists, descended on me to explain further. Erwin Hahn, who was watching, later told me that I got a 'Nobel grilling'! The group, however, soon lost interest in what I was trying to say and began arguing among itself. I finally walked away. The success therefore had an intense personal meaning to Al, Tom, and me.

CONDUCTION ELECTRON SPIN SUSCEPTIBILITY

One of the most important results of the Pauli exclusion principle is its effect on the predictions of the free electron theory of metals. Pauli showed that the spin susceptibility of metals was greatly reduced, as well as becoming independent of temperature rather than obeying Curie's law. One day in the fall of 1953, I encountered Dave Pines in the hallway outside my lab. He had recently come as a postdoc to work with John Bardeen. Dave's interests were many-body physics, especially electrons in solids, dating from his graduate study with David Bohm at Princeton. He was excited because he had just succeeded in calculating the many-body corrections to the Pauli susceptibility. The corrections were significant, though not large. He bemoaned the fact that there was no way of measuring the Pauli susceptibility by itself. Susceptibility measurements gave the sum of the spin and orbital contributions. Since the electron orbital contributions were large and only crudely known theoretically, one could not reliably subtract them from the measured total susceptibility.

When I was a graduate student, I had learned the Kramers–Kronig relationships. In particular, I knew that the static spin susceptibility was proportional to the area under the absorption curve with known constants of proportionality. Purcell had pointed out that relationship to me. I had used

that relationship in a term paper I wrote for the great Dutch physicist Professor C. J. Gorter, who lectured at Harvard in the summer of 1947, to estimate from the known susceptibility the expected ESR signal strength for my Ph.D. thesis. On the spot I told Dave 'I know how to do it. We will measure the area under the conduction electron spin resonance. We will not measure the area in absolute terms. Rather, we will compare the absorption area with that of the host nucleus. We can observe them both at the same frequency, in the same rig, in the same sample by simply changing the strength of the static magnetic field.' The whole experiment just popped into my mind at once—because I had been thinking of doing CESR in an NMR rig at low fields, and because with Dick Norberg and Don Holcomb I had been doing NMR in Li and Na.

I had a new student, Bob Schumacher, in my group. We immediately set to work on the experiment. I actually built a special NMR rig for the experiment, and we operated without a bridge so that we could be sure we measured absorption not dispersion. This concept arose from the method I had employed in my thesis of running a magic tee bridge with a microwave cavity at resonance, but mismatched to the waveguide. Bob completed the results for Li at room temperature. The Na CESR line was too broad at room temperature but much narrower at liquid nitrogen temperature. We did not have a liquid nitrogen dewar. It was typical of Bob that he fashioned a simple one consisting of a glass vial containing the sample which rested on a brass bar which dipped into a liquid-nitrogen-filled cavity scooped from an insulating material called florafoam. With this he measured the Pauli susceptibility of Na.⁷

SUPERCONDUCTIVITY

Shortly after we did the Overhauser effect and spin susceptibility experiments, John Bardeen gave a physics colloquium in which he described a theory of superconductivity. This theory preceded the famous Bardeen, Cooper, Schrieffer (BCS) theory. In his talk he stated that the superconducting transition involved changes which occurred for electrons whose energies were close to the Fermi energy. I did not understand his talk in any detail, but I was instantly struck by the concept of changes near the Fermi energy since I knew from all the work I have just described that these were the electrons which provided the spin–lattice relaxation for nuclei in a metal. Clearly, if electrons at the Fermi surface underwent a change, the nuclear spin–lattice time should change. As I sat there in the audience, excited about a possible experiment, I recalled that a superconductor excludes magnetic fields (this was before Type II superconductors were known). How then could one measure a nuclear relaxation time? By then, I had quit listening and was engrossed with the puzzle. One could make particles smaller than the superconducting penetration depth—but that was technically very hard. Then I thought of field cycling: start with a magnetic field, H_0 , sufficiently strong to suppress the superconductivity. Turn off the field, causing the sample to go superconducting, and cooling the nuclear spins (an adiabatic demagnetization). After sitting at zero field for a time, turn the magnet back on. The sample then would become normal and one could quickly inspect the nuclear resonance. If the nuclei warmed while H_0 was zero, they would be hotter when H_0 was turned on than they were before it was turned off and the

resonance amplitude would diminish. By measuring resonance amplitude versus the time in zero field, one could deduce the relaxation time in zero field. By the end of John's talk, I had an outline of what to do.

I was fortunate in having a very able new student, Chuck Hebel, who had just joined the group. He was eager to work on the experiment. We realized that we needed a nucleus with a sufficiently slow relaxation time compared with the time it would take to turn on (or off) the magnetic field, H_0 . ^{207}Pb or ^{199}Hg had convenient superconducting transition temperatures, but their spin–lattice relaxation times were much too fast compared with the time to turn on or off a magnet. ^{27}Al , however, had a much longer T_1 value (about 1 s at 1 K) and a convenient critical field (98 G at 0 K), so that we could suppress the superconductivity without applying too strong a static field. Its principal difficulty was that its superconducting transition occurred at 1.172 K, a very difficult temperature to reach in those times before the discovery of He dilution refrigerators. No one in my group had ever done an experiment with liquid He before. However, my colleagues, Dillon Mapother and John Wheatley were specialists in low temperatures, so we felt confident of good help.

We chose a magnetic field for resonance of 360 G (putting the ^{27}Al resonance at 400 kHz) to minimize the size of the magnetic field we had to turn off and on. Of course, no one else was doing NMR at such low frequencies, but we felt that with the assistance of the large Boltzmann factor at 1 K, and based on our experience with protons at 50 kHz in our Overhauser effect experiment, we could do the experiment.

We considered building a solenoid for producing H_0 , but when we learned that there were some thin iron sheets left over from building the giant Betatron here in Urbana, we instead chose to build a laminated iron magnet.

The field-cycling concept was based on the idea that we were doing an adiabatic demagnetization, a reversible process in the thermodynamic sense. Thus if one turned off the field, the spin temperature would drop, but if we turned the field back on without spin–lattice relaxation having occurred, we would return the spins in high field to their original spin temperature. If one switches the field too fast, this condition is violated. Of course, the big unknown was whether when the sample turned superconducting it would let the nuclear spins act reversibly. There is an extensive discussion of such issues in our *Physical Review*.⁸

The most difficult problem we faced was how to cool the sample. There were two alternatives: pumping on the liquid helium bath or building an adiabatic demagnetization refrigerator. The latter approach seemed too formidable given all the other difficult experimental tasks we faced. Mapother and Wheatley explained how we could construct a special pumping scheme to overcome somewhat the limitations involving the Rollin film. Chuck built a three Dewar system: the outer one contained liquid nitrogen, the second Dewar contained liquid He at 4.2 K, as well as the sample coil and leads, and a third Dewar, inside the second one, contained the sample. The system was pumped through two 1-mm constrictions to cut down the flow from Rollin film. We were able to achieve 0.94 K by this method.

Redfield and Anderson independently conceived of the same experiment. They were a bit behind us in time. They built an adiabatic demagnetization apparatus which enabled them to

get to much lower temperatures than we could, and thus were the first to obtain results for temperatures well below T_c .

We built the complete NMR rig from scratch. The full field of the magnet was 450–500 G, but we observed the resonance ‘on the fly’ as the magnet was turned on at the end of the demagnetization cycle as it passed through the 360 G point corresponding to the 400 kHz ^{27}Al resonant frequency. We also faced a theoretical problem. The conventional theory of spin–lattice relaxation is based on strong field quantization, but we were going to measure relaxation in zero applied field for which the eigenstates were unknown and thus there was no theory. While Chuck was building the rig, I struggled with that problem. Fortunately, I had taken a course taught by Professor C. J. Gorter in the summer of 1947 when he was a visitor at Harvard. He made the class familiar with the beautiful Dutch work on paramagnetic relaxation and how they had used spin temperature to analyze it. I had also studied for my Ph.D. thesis Van Vleck’s famous paper on electron relaxation times in Ti and Cr alum in which he showed how by using the concept of spin temperature plus trace methods one could calculate a relaxation time without knowledge of the eigenstates of the system. That proved to be the key to calculate relaxation under the sole influence of a dipolar Hamiltonian. We explored the normal state relaxation time at zero field, and also the field dependence to check our general understanding, then tackled the superconductor (as I recall in the fall of 1956).

Our earliest thinking about how superconductivity would affect the relaxation rate was based on the Gorter–Casimir two-fluid model which led us to expect that only the normal fluid would relax the nuclei, so that the spin–lattice relaxation rate would get progressively longer as we went to lower and lower temperatures. We were therefore amazed when we discovered that the relaxation rate was faster in the superconducting state than in the normal state. At that time, the concept of the energy gap was in the air. In fact, Bardeen had shown in 1955 that if one assumed an energy gap one would probably get the Meissner effect. Chuck and I had seen that paper. We therefore tried just putting a density-of-states function which had a gap, with the missing states piled up at the edge of the gap, in the usual classical expression for the spin–lattice relaxation rate of nuclei in a metal. This approach had all the desired properties: an enhanced relaxation rate just below T_c , a diminished rate far below T_c (a result Reif had found for colloidal Hg).

We showed the calculation to Bardeen, who said the model looked reasonable. With the simple density of states function, however, we did not get as large an enhancement just below T_c as we had found experimentally.

At about this time, Cooper made his famous discovery of Cooper pairs (that was submitted for publication in September 1956). Then one morning in early February 1957, John Bardeen stopped me in the hallway of the Physics building. It was clear that he wanted to talk, but it seemed as though we stood there for minutes before he said ‘Well, I think we’ve solved superconductivity’. Evidently, the previous evening he, Bob Schrieffer, and Leon Cooper had succeeded in calculating the ground-state energy and some other properties. I believe I was the first person apart from them (and perhaps John’s family at breakfast) to learn of this breakthrough. John told me succinctly the essence of what they had done. Then in a day or two he gave me a draft of their first submission (received Feb. 18, 1957 at the *Physical Review*). At that time, BCS had not

yet developed the equations for $T > 0$, but that work followed quickly.

John showed me their Hamiltonian and wavefunction. It was all in the language of annihilation and creation operators which I had never used. I resolved to try to calculate the spin–lattice relaxation. First, to test what I was doing, I tried to calculate the relaxation time in a normal metal by means of these operators. That was successful. I next tried the calculation with the superconducting wavefunctions. I suggested to Chuck that he do both these calculations too, so we could check each other. To our surprise, we found two terms which connected the initial and final states. We discussed these with Bob Schrieffer, thinking that we must be making a mistake. Meanwhile, he, Bardeen, and Cooper were analyzing a number of other experiments, such as ultrasonic absorption and microwave transmission. They found that all these rate processes had two terms, but they could in some cases add (e.g. NMR) and in others subtract (ultrasound) giving very different temperature dependences below T_c . They explained to us that our experiment when contrasted with the ultrasonic attenuation results of Morse and Bohm, or of Bommel, gave proof of the BCS pairing condition. This was indeed a thrill for Chuck and for me.

PHASE-COHERENT DETECTION AND PULSE SIGNAL AVERAGING

From the first studies by Dick Norberg of ^1H in Pd wires, we realized that there was substantial noise present which limited the precision of measurement. This problem was dealt with in steady-state experiments by the use of lock-in amplifiers and field modulation to achieve narrow frequency bandwidths. Pulse systems are necessarily broadband in order to follow the rise and fall of the echo. Clearly we needed to average the results of a number of echoes to improve signal to noise. In our first efforts, we took multiple exposure photographs of scope screens, adjusting the spot intensity so that the ‘heavily repeated’ values of detection were featured. However, by the time in 1952 and 1953 when Don Holcomb and Dick Norberg were studying diffusion in the alkali metals, we decided we needed an electronic method of recording echo signals on a meter, analogous to the use of lock-in amplifiers with meters or chart recorders used in steady-state resonance. Dick Norberg did some inquiries which led us to the so-called box-car circuit, which was a gated voltmeter which stored the input voltage during the gate interval on a capacitor. By adjusting the charging time constant of the capacitor, one could control the effective number of echo signals which contributed to the signal.

The use of the box-car gave us the ability to average, but it still suffered from two deficiencies. The actual echo signal consisted of a radiofrequency voltage whose envelope rose from zero up to the echo peak and then fell to zero. Superposed was a noise voltage amplified from the input of the radiofrequency amplifier. Thus, the noise consisted of radiofrequency voltages which extended across a band of frequencies determined by the amplifier gain. The noise voltage and the signal voltage were simultaneously present. Their sum was then rectified by a diode in series with a parallel resistor, R , and a capacitor, C . The RC time constant was

adjusted to allow the rectified voltage to follow the rise and fall of the echo envelope.

The first deficiency was that the diode rectification signal at low voltages was not proportional to the amplitude of the input voltage. Thus, even without noise, the output was not a faithful reproduction of the input. This defect led to spin–lattice relaxation curves which were not exponential. Don Holcomb dealt with this defect by a calibration method (output voltage versus input).

The other defect was that when the noise exceeded the signal, the presence of signal could produce either a positive output (if signal and noise were in phase) or a negative output (if signal and noise were 180° out of phase). Thus, averaging N echoes did not give N -times the signal of one echo.

Norberg, Holcomb, and I realized these defects, and that the way to overcome them was to use a phase-coherent system. Such a system was constructed by my student John Spokas for his thesis studying diffusion in Al metal by doing NMR up to 1000 K. The concept was to have a stable oscillator which ran continuously. To generate the rf pulses, we passed that signal through a gated amplifier. At the receiver diode, we inserted a reference signal of adjustable phase in series with the signal. As long as the reference voltage was kept large compared with the signal voltage, the operation was linear and noise signals were equally positive and negative. (Subsequently we went to a balanced mixer to reduce the effect of noise on the reference signal source.) By adjusting the phase of the reference signal, one could pick out NMR signals which had any desired phase with respect to the alternating magnetic field of the pulse. This basic system enabled John Spokas to record with good signal-to-noise echo signals which were only a few per cent of the peak value at temperatures close to 1000 K. John's experiment was the first pulsed NMR experiment in which signal averaging was applied to signals which were much smaller than noise.⁹

Today these systems have been greatly improved by using analog-to-digital conversion of the signals, and by recording simultaneously two channels in which the reference signals differ by 90° phase shift (quadrature detection).

CONCLUSION

Preparing this account has caused me to relive a very exciting time in the history of magnetic resonance. I have enjoyed describing how associations with my colleagues were essential in stimulating the ideas for our experiments. I have again felt the joy of working with a wonderful group of students, each so different from the others, each contributing such unique strengths to our common endeavors. To be launched into orbit by two such teachers as Van and Ed Purcell was a very special privilege. I have tried to transmit their spirit and approach to science to each of my students.

Smith, Ian C. P.: Deuterium NMR: Reflections on its Evolution

Ian C. P. Smith

NRC Institute for Biodiagnostics, Winnipeg, Canada

In the early 1970s, when the first multinuclear MR instruments were under development, the perception of the utility of ^2H NMR was such that this nucleus was relegated to be the universal nucleus for field/frequency locking. This unfortunate choice in large part excluded the use of ^2H NMR by any but those inclined to modify their instruments themselves.

Despite this problem, the 1970s saw significant activity in the direct observation of ^2H . In 1976, a group of us at NRC were asked to review all applications to date. We finished the article in 1977,¹ having reviewed some 350 publications. Even so we missed a few where ^2H did not figure prominently in the title or key words. This literature survey demonstrated a very useful role for ^2H NMR in chemistry and a promising future in biochemistry.

The most dramatic contribution of ^2H NMR in biochemistry is undoubtedly in the field of biological membranes. These contain a considerable proportion of fatty compounds such as phospholipids and cholesterol. NMR studies of membranes by the usual ^1H or ^{13}C techniques appeared to be impossible due to the diversity of molecular species and the expected very large resonance widths.

Discussions with Dr. Kjeld Schaumburg, University of Copenhagen, led us to attempt the labeling of specific components of membranes with ^2H and to tackle the experimental difficulties associated with the expected short T_2 values, long T_1 values, and broad resonances. Our early efforts led to measurable broadline patterns² (Figure 1) from which the ordering of lipids within model membranes could be measured, but we knew that we were losing much signal due to our inability to sample early points in the free induction decay. Discussion with Drs. Myer Bloom and Jim Davis at the University of British Columbia led to the modification of our instrument to perform quadrupole echoes. Collaborations with the UBC group led to our incorporating ^2H -labeled lipids into a complex biological membrane, that of *Acholeplasma laidlawii*, and the measurement of the ordering for individual positions within the lipids.³ Finally, by attention to probe characteristics and increased rf power, we were able to observe the 'invisible' lipids—those which gave no spectrum in conventional spectrometers below certain 'melting' temperatures (Figure 2).⁴

Developments in this area were proceeding concurrently in the laboratories of Dr. Joachim Seelig, University of Basel and Dr. Eric Oldfield, University of Illinois. Seelig specialized in both biological applications⁵ and theoretical interpretations,⁶ whereas Oldfield performed a wide variety of applications.⁷ The University of British Columbia group collaborated with a number of laboratories on biological applications.^{8,9} A variety of biological applications were ultimately performed by Dr. Anthony Watts, Oxford University.¹⁰ Our laboratory

Figure 1 ^2H NMR spectra (15 MHz) of *N,N,N*-trimethyl- d_3 -phosphatidylcholine, 32 mg ml^{-1} in aqueous dispersion at 31°C . Unsonicated, 11 000 transients; sonicated, 500 transients (reproduced from Ref. 2 with permission)

eventually turned its efforts toward the carbohydrate head groups of lipids which are responsible for immunological recognition.¹¹

Deuterium NMR is now a fruitful and mature tool in the fields of chemistry, biochemistry, and biophysics. It has been a pleasure to be part of the group of scientists who contributed to the achievement of this success. In particular, the collaborations with Drs. M. Bloom, H. H. Mantsch, H. Saitô, K. Schaumburg, and J. Seelig are much appreciated.

Spiess, Hans Wolfgang: Multidimensional Solid State NMR of Polymers

Hans Wolfgang Spiess

Max-Planck-Institut für Polymerforschung, Mainz, Germany

INTRODUCTION

NMR of polymers is divided into two major areas. From the *chemist's* point of view, high-resolution NMR provides detailed information about the chain microstructure in solution. This field was pioneered by F. A. Bovey at Bell Labs and quickly developed into an indispensable tool of polymer chemistry. From the *materials science* point of view, many of the macroscopic properties of polymers arise from the organization of macromolecules in the bulk. Therefore, experimental techniques are needed that can characterize the behavior of polymers on a molecular level and on mesoscopic scales in order to relate such behavior to macroscopic properties such as mechanical, electrical, optical, and transport. In particular, NMR by its very nature can provide information about molecular dynamics, molecular order, phase separation, and interfacial effects by exploiting the various anisotropic spin interactions in the solid state.

Hence, besides high-resolution NMR of polymers in solution, wide-line NMR of bulk polymers was developed based on the dipole–dipole interaction of protons. However, in contrast to the situation in liquids where the detailed information about chain microstructure available through high-resolution NMR is unique, solid state NMR competes with well-established techniques such as light, X-ray, or neutron scattering, electron microscopy, and dielectric or mechanical relaxation. In order to compete favorably with these techniques, the potential of solid state NMR has to be fully exploited.

The obvious advantage of NMR is its extreme selectivity, since specific chemical, motional, and orientational sites can be investigated. Thus, the advent of high-resolution NMR in solids by the use of multiple pulse irradiation, high power decoupling, and magic angle spinning (MAS) also opened up new possibilities for the NMR of polymers. As far as dynamic processes are concerned, advanced NMR techniques even offered the challenge of unraveling information inaccessible by other methods. This article describes our efforts to develop solid state NMR techniques so as to achieve this goal, and indicates how far we have progressed to date and what we think the prospects are for the future.

PULSED DEUTERON NMR: TIMESCALE OF MOLECULAR MOTIONS

In bulk polymers, *molecular dynamics* are slowed down resulting in correlation times of the order of seconds or even longer. This holds, for example, for vitrifying polymer melts when approaching the glass transition temperature T_g .

Moreover, the mechanical properties of solid polymers depend mainly on slow motions with correlation times above 1 ms or so. Consequently, dynamic mechanical testing devices often work with frequencies below 1 kHz. In the early 1970s, such slow motions could not be characterized in any detail via NMR. Apart from ^1H NMR wide-line techniques, measurements of spin–lattice relaxation in the laboratory or rotating frame were employed to detect motions with rates above 10 kHz. In principle, measurements of T_{1D} , the spin–lattice relaxation of dipolar order among the protons, could have provided a means for studying slower motions, but these lacked the selectivity to enable definite conclusions to be reached.

Why Deuteron NMR?

In the early 1970s, high-resolution ^{13}C as well as ^1H NMR in solids were still in their infancies and required investigators with considerable rf expertise. When I joined Hans Sillescu, who had just moved to Mainz as a full professor, we discussed setting up a laboratory for high-resolution NMR in solids using the ^1H multiple pulse and ^{13}C NMR techniques I had become acquainted with at the Max-Planck-Institut in Heidelberg, working with Ulrich Haeberlen in the group of Prof. K. H. Hauser. However, it was clear to us that we would not have a chance of competing with other groups, since a suitable spectrometer was not available and funds were limited. However, I was more than willing to take up his interest in deuteron (^2H) NMR and agreed to record ^2H NMR spectra by Fourier techniques despite the fact that nobody at the time knew how to do this because the Pake pattern for the $I = 1$ spin of ^2H is exceedingly broad in rigid solids and covers a width of about 250 kHz.

The reasoning for our decision was very simple. If FT ^2H NMR, which had already shown its value in studies of liquid crystals and lipids where the spectra are somewhat narrowed, could be extended to solid polymers, the selectivity needed to study synthetic polymers could be achieved by chemical means, i.e. by selective deuteration, and Hans Sillescu had already developed considerable expertise in this area.

Thus, rather than trying to incorporate methods for studying slow motions directly into sophisticated high-resolution techniques, we set out first to develop such methods independently for ^2H NMR. This meant that we could work with a single frequency, rather than double resonance, a few rf pulses rather than multiple pulse trains, and avoid limitations imposed by the mechanical rotation in MAS. Moreover, selected C–H bond directions are monitored in ^2H NMR providing well-defined indicators of polymer orientation and dynamics. If this proved successful, the means of obtaining dynamic information through ^2H NMR could then be incorporated into ^{13}C and ^1H NMR at a later stage. In fact, a similar approach was being pursued by Robert Griffin at the Francis Bitter National Magnet Laboratory (MIT) in Cambridge, MA, while developing solid state NMR methods for biophysics.

Rigid Solid Spectra

The faithful recording of FT ^2H NMR spectra covering the full spectral width in solids turned out to be easier

than anticipated. After unsuccessful attempts employing two frequency synthesizers (one for irradiation, the other for detection) we made use of the simple fact that 'the narrower the pulse, the broader the excitation spectrum'. Thus rather than employing a $90^\circ_y - \tau - 90^\circ_x$ solid-echo sequence, we reduced the pulse width to $45^\circ_y - \tau - 45^\circ_x$ at the expense of the echo signal intensity. As always, we needed a suitable model system to test the idea, namely a rigid solid for which a Pake pattern was anticipated. This turned out to be hexamethylenetetramine (HMT), which we had studied before by wideline techniques. Notably this tetrahedral molecule is an analog of adamantane, the 'drosophila' of ^{13}C NMR in solids and was also used later to test our ideas for studying slow motions.

The first FT ^2H NMR spectrum of HMT covering the full spectral width of 250 kHz¹ is reproduced in Figure 1(a). The advantages of Fourier spectroscopy in terms of signal-to-noise ratio were readily exploited by recording the temperature-dependent ^2H NMR spectra of semicrystalline polymers such as polyethylene² [see Figure 1(b)]. They are superpositions of a broad Pake pattern and partially narrowed lines. Thus, they nicely display the different chain mobilities in the crystalline and amorphous regions. Dietmar Hentschel, the graduate student involved, was extremely pleased that in 1 day he could now record a whole series of such spectra, which before had taken him weeks on a CW wideline spectrometer.

Solid Echoes in the Presence of Motion

The information available from pulsed ^2H NMR goes far beyond recording wideline spectra. To any sensible NMR spectroscopist, it is obvious that by recording the FT of the solid echo as a function of the pulse spacing τ , *transverse relaxation* can be studied. However, this did not seem to be particularly interesting, since transverse relaxation was expected to be governed by the weak and rather unspecific dipole-dipole coupling of the deuterons among themselves and with protons.

During a visit I made to his lab, Bob Griffin drew my attention to the fact that the experimental ^2H solid echo spectra

of lipids in the gel phase deviate considerably from those expected for a rigid solid and, moreover, the lineshape depends on the pulse spacing τ . Although I could not immediately come up with an explanation, the problem of 'echo distortions' was easily solved after I returned home. I suddenly realized that Hans Sillescu had the theory for the dependence of the echo signal as a function of τ worked out already for the motional model of isotropic rotational diffusion. In fact, that problem had already been treated for the time domain in 1969 by D. Woessner et al. However, the chain motion of hydrocarbons, lipids, and polymers alike, was commonly considered as involving kinks and jogs etc., leading to an exchange of C-H bond orientations between only a limited number of sites. Thus at lunch one day I proposed to extend the well-known Anderson-Weiss treatment of spin exchange between two sites to include the formation of an echo. With the limited computational power available in the early 1980s an efficient algorithm for calculating powder lineshapes required an analytical solution. Derivation of this formula turned out to be so easy that I had it worked out the same afternoon and the paper presenting simulated lineshapes for the kink motion (or *trans/gauche* isomerization) was submitted only a week later.³ Because this simple analytical formula is so much easier to handle numerically than the full treatment of the problem through the stochastic Liouville equation, it has been widely applied in trying to model experimental spectra. In fact, in some cases various authors have proposed simple two-site models of molecular dynamics which seems to indicate their appreciation of a simple computer program rather than a physical insight into the certainly more complex process under study.

First Applications in Polymer Science

However, it has turned out that in synthetic as well as in biopolymers at least one process exists which is often observed and involves a two-site jump when probed by ^2H NMR, namely the phenyl flip (rotation about 180°)⁴ [Figure 1(c)]. I

Figure 1 Examples of early FT ^2H NMR spectra. (a) Hexamethylenetetramine, (b) polyethylene and (c) polycarbonate

'stumbled' on this process when we started a common project with Prof. E. W. Fischer in Mainz, trying to elucidate the molecular motions responsible for the favorable mechanical properties of glassy polycarbonate, a polymer now known to virtually everyone as the material of compact discs. Fischer was highly skeptical when I first told him that we had found phenyl flips in polycarbonate and readily demonstrated to me how improbable the process would be by the use of a Stuart–Briegleb model of the repeat unit: one person had to hold the bisphenol unit of polycarbonate with two hands while another tried to crank a phenyl ring. Rather than flipping the ring, this procedure would typically break the device that mimics chemical bonds in the model. When that happened, Fischer looked at me and asked 'and you are telling me that you have observed phenyl flips'. This little story demonstrates one of the beauties of solid state NMR, i.e. results are obtained directly, without the need of an a priori knowledge about the probability of a dynamic process. In fact, Prof. Fischer's original skepticism quickly vanished. Not only did he accept our experimental observations, but I feel that this example made him appreciate the potential of solid state NMR and eventually led to the fact that we are now colleagues at the Max-Planck-Institut für Polymerforschung in Mainz, which was founded shortly thereafter.

Until then, phenyl flips had not been considered seriously as an interesting aspect of polymer dynamics. After they had been 'discovered' by ^2H NMR and later confirmed by

^{13}C NMR (Alan Jones, Jake Schaefer), they turned out to be ubiquitous and closely related to the mechanical behavior of polymers. In fact, most high strength polymeric materials contain phenyl rings and today the question of whether or not phenyl flips occur in such systems is routinely answered by ^2H NMR even in industrial laboratories. Furthermore, pulsed solid state ^2H NMR was quickly accepted as a powerful tool for studying chain motions and orientational effects in synthetic polymers, lipids, and even proteins. Thus, within five years or so, it developed into what is sometimes called a 'standard technique'.

Spin Alignment

Despite these successes in polymer science and in biophysics, ^2H solid echo spectroscopy only provides information about relatively fast motions on timescales below 1 ms or so. Again, it should have been obvious to experienced NMR spectroscopists how the time range could be extended to include longer times by applying three pulses such as Erwin Hahn's stimulated echo sequence of 90° pulses⁵ or the Jeener–Broekaert sequence involving 45° pulses⁶ (Figure 2). Again, I have to admit that rather than planning it, I stumbled over this possibility when adjusting the solid echo sequence with 45° pulses. Puzzling behavior was sometimes observed when changing the sequence within a second or so. Knowing how effective 45° pulses are in creating dipolar order, it

Figure 2 Elucidation of molecular dynamics by pulsed NMR. Relation of molecular orientation, ^2H NMR spectra, and pulse sequence

did not take long to work out the mathematics for generating 'quadrupolar order' or *spin alignment* for the spin $I = 1$ nucleus of ^2H .⁷ Although in our model system, HMT, we could follow the tetrahedral motion over eight orders of magnitude, including the 'ultraslow' region with only one jump per minute, applications of the spin-alignment technique to polymers were limited because the molecular dynamics there is rather complex.

TWO-DIMENSIONAL EXCHANGE NMR: GEOMETRY OF MOLECULAR MOTIONS

The use of three-pulse sequences (Figure 2) for detecting slow dynamic processes offered the possibility of extending this technique to the *two-dimensional exchange NMR of solids*. However, it was not until I could set up my own research group at the Max-Planck-Institut für Polymerforschung that we actually attempted to record such a 2D spectrum. Again, the choice of a suitable model system was crucial. Figure 3(a) shows the ^2H 2D exchange spectrum of dimethyl sulfone (DMS), recorded by Claudia Schmidt as part of her Ph.D. thesis.⁸ Here the ^2H spectrum is narrowed by the methyl rotation which also leads to a convenient spin-lattice relaxation time at room temperature. The two-fold jump motion of the molecule noted earlier by Dave Grant and co-workers manifests itself in a well-defined elliptical ridge pattern, which directly projects the angle by which the S-C bond has rotated into the 2D spectral plane. There it can be read off with a ruler. That immediately showed that 2D exchange NMR provides unique information about the *geometry* of rotational motions, independent of model assumptions.

Of course, a number of difficulties had to be overcome before a 2D spectrum of this quality was obtained. In fact, when we first recorded a 2D exchange data set of DMS, and processed it to generate a power spectrum by standard software, a pattern full of artifacts, such as t_1 ridges, etc., resulted. However, it also revealed a curved feature and we did not know of any artifact which could be responsible. We realized that a pure absorption mode spectrum was required in order to reveal faithfully the exchange spectrum. However, without knowing what to expect, it proved virtually impossible to achieve the proper phasing of the 2D data set that we subsequently recorded to this end. We thought that a theoretical calculation of the spectrum would be difficult⁹ and for this reason we had never attempted to undertake this. As is often the case under such circumstances, a fresh approach was necessary. Thus, shortly after the Christmas break in 1985, I suddenly realized that I had already calculated individual slices of such a 2D exchange spectrum several years previously, when I had analyzed the ^2H lineshapes of partially ordered polymers based on conical distributions.¹⁰ Within one day we had identified the curved feature mentioned above as part of the elliptical pattern and within three months Claudia Schmidt had developed the software for data processing.

Besides being highly informative, 2D exchange spectra look pretty and this turned out to be a considerable advantage either when presenting them at scientific meetings or to funding agencies. Within a few years, 2D exchange NMR of deuterons revealed detailed information about the timescale

and geometry of chain motion in crystalline and amorphous polymers, both in the solid state and at the glass transition. I had the privilege of supervizing three outstanding graduate students who developed the theory for analyzing such spectra (Stefan Wefing), implementing the technique with MAS NMR (Alfred Hagemeyer), and extending it to ^{13}C NMR (Klaus Schmidt-Rohr).

EXTENSION TO HIGHER DIMENSIONS AND TO OTHER NUCLEI

An example of a 2D ^{13}C NMR spectrum of polyoxymethylene recorded by Klaus Schmidt-Rohr is displayed in Figure 3(b).¹¹ The exchange pattern results from the helical jump motion of the polymer in its crystalline regions. Thus, although it had taken almost a decade to establish pulsed ^2H NMR as a powerful tool for studying molecular dynamics, the development of two-dimensional exchange NMR techniques was not restricted to ^2H NMR but was quickly applied to ^{13}C NMR. In his thesis Klaus Schmidt-Rohr also extended exchange NMR to three dimensions [Figure 3(c)]. This allows one clearly to distinguish different *motional mechanisms*, because the orientation of a given unit is probed at *three* subsequent points in time. This unique technique reveals the fundamental differences between the chain motion in crystalline and amorphous polymers. He pushed the technique further to record the reduced 4D exchange NMR spectra which provided previously inaccessible information about the nature of the nonexponential relaxation of polymers above T_g .¹²

Last, but not least, Klaus Schmidt-Rohr designed a simple version of heteronuclear NMR, 2D WISE NMR, allowing separation of the ^1H wideline spectra for the protons attached to different carbons in the structure under study.¹³ This provides dynamic information with a selectivity equivalent to or sometimes even higher than ^2H NMR of selectively deuterated polymers. Moreover, by exploiting spin diffusion we are now able to associate different mobilities with corresponding length scales in heterogenous polymers.

Thus, about 15 years after we started, we have now extended our experience gained in the studies of ^2H labeled materials into high-resolution NMR of solids, as originally planned. Since these techniques do not require isotopic labeling, they are widely applicable to academic and industrial research alike.

COMPARISON WITH OTHER METHODS OF POLYMER CHARACTERIZATION

As stated in the Introduction, the solid state NMR of polymers competes with other well-established and highly informative techniques of polymer characterization. In fact, a considerable impetus for the methodological developments described above came from the often expressed expectation that a new insight into polymer dynamics could only be obtained by neutron *scattering*. Again, a comparison of the information available from pulsed NMR with that provided by scattering techniques should have been the obvious course. However, it took a person like Franz Fujara with experience

Figure 3 Examples of multidimensional exchange NMR spectra. (a) 2D ^2H spectrum of dimethyl sulfone; (b) 2D ^{13}C spectrum of polyoxymethylene; and (c) 3D ^{13}C spectrum of drawn polyoxymethylene

in both fields to realize the subtle analogy between three-pulse (spin alignment) experiments and incoherent neutron scattering.¹⁴

The analogy between NMR and scattering is far more general than first thought. It is based on the fact that plane waves contain *two* Fourier pairs, viz, time/frequency and position/momentum. Thus two-dimensional NMR exploiting angular-dependent frequencies provides information in orientational space which is completely analogous to that available in reciprocal space through scattering. This has recently been pointed out concerning the determination of orientational distribution functions by 2D NMR relative to the pole-figure analysis in wide-angle X-ray scattering,¹⁵ see Figure 4, and is alluded to in detail in a monograph.¹⁶ While structural determination by scattering is largely restricted to crystalline materials, multidimensional NMR also provides detailed information about chain order in amorphous polymers. Hence, it is applicable to a considerable variety of systems including liquid crystalline polymers from laboratories or from industrial process lines.

As far as electron microscopy is concerned, NMR cannot provide highly resolved images of polymer morphology capable of competing with that technique. Nevertheless, high-resolution NMR in solids now offers a means of monitoring spin diffusion in considerable detail and the accurate determination of domain sizes in heterogeneous polymers.¹⁷ In fact, NMR can provide quantitative information about nanoheterogeneities, due to concentration fluctuations on length scales of a few nm which are difficult to ascertain by X-ray scattering and electron microscopy. In addition, interfacial regions at internal surfaces can be characterized. Most importantly, NMR not only yields information about domain sizes and diameters of interfaces, but also provides detailed information about the motional behavior in the various phases.

The timescale over which NMR provides detailed information about molecular dynamics has been extended by introducing multidimensional techniques to cover about 14 orders

of magnitude, from 10^{-12} s to 100 s. Thus molecular processes responsible for dielectric or mechanical *relaxation* phenomena can now be directly identified.

SUMMARY AND OUTLOOK

In order to compete favorably with established techniques of bulk polymer characterization, solid state NMR has to provide unique information inaccessible by other methods. The development of multidimensional solid state NMR has certainly achieved this goal in so far as molecular dynamics are concerned. It yields high order correlation functions which provide stringent tests for theoretical models of dynamic processes in viscous systems. In particular, multidimensional solid state NMR delivers information about molecular dynamics which is direct and free of model assumptions. Thus it is not necessary to wait for theory to

Figure 4 Analogy between wide-angle X-ray scattering and 2D exchange NMR

provide a model that can be tested experimentally, but instead it is possible to provide experimental data that can act as a challenge to theory or molecular modeling by computer simulation.

As far as polymer structure is concerned, multidimensional NMR provides information which supplements that accessible from scattering or microscopic techniques. In fact, after lectures on multidimensional solid state, NMR, I am sometimes asked: 'Are there any problems that cannot be tackled by NMR?' Of course, there are many, but we are working on them. For example, methods are being developed to probe the extent to which rotations of adjacent groups in the solid are *correlated*. Eventually one would like to obtain the information about molecular structure and dynamics accessible by solid state NMR not only for the sample as a whole but *spatially* resolved. One would like to distinguish the molecular parameters in regions close to the surface from those in the bulk. For this reason, together with Bernhard Blümich, we have set out to record spatially resolved solid state NMR spectra of polymers, employing imaging methods. As a first example, a spatially resolved ^{13}C NMR spectrum of a drawn polypropylene sample¹⁸ is shown in Figure 5. It reflects differences in density and chain alignment between skin and core due to the processing and demonstrates that spectroscopic NMR imaging of solids is indeed possible.

Looking back to the 1970s, solid state NMR of polymers has come a long way. A wealth of information about polymer structure and dynamics is now available through advanced multidimensional techniques. Important correlations between macroscopic and molecular behavior are emerging from such studies. Examples are helical jumps or defect diffusion in crystallites, specific local motions in amorphous polymers, and conformational transitions coupled to relaxations of larger chain units in highly viscous polymer melts. Indeed, the results available to date have provided the basis for an extended monograph on the subject.¹⁶ Such information has already been used successfully in the design of polymers with improved properties. Thus it can be anticipated that the importance of multidimensional solid state NMR in materials science and in biophysics will increase substantially in the future.

Figure 5 (a) Spatially resolved ^{13}C spectrum of drawn polypropylene; (b) geometry of sample

This article has tried to tell the story of our efforts in the development of multidimensional NMR as a new tool for polymer characterization. It is obvious that a whole research group has been involved and not just a single person. Moreover, other groups have made substantial contributions to the field but are not included here. As far as my own role is concerned, it was that of an active group member in the beginning, where I was actually doing experiments and calculations myself. My role has shifted into supervising my group and sometimes only trying to understand what my co-workers have done. Thus it is my pleasure to thank all my colleagues who have been involved in an endeavor which has sometimes been frustrating but more often stimulating and a lot of fun.

Stejskal, Edward O.: Reminiscences about the Development of Pulsed Field Gradient, Spin-Echo NMR (PFGSE NMR)

Edward O. Stejskal

North Carolina State University, Raleigh, NC, USA

John Tanner joined my research group in the Department of Chemistry at the University of Wisconsin, Madison at the beginning of 1962. Shortly before that time he had been working at a small technology-based company on the outskirts of Madison. He had been working with gelatin–water solutions over a wide range of concentrations. Above a certain concentration, these solutions gel and the viscosity rises rapidly. However, the small water molecules can still pass between the strands of the gel and, therefore, their mobility need not drop off as fast as the viscosity rise would indicate. He proposed to me that he could study the breakdown of the relation between bulk viscosity and water mobility if he could measure the diffusion coefficient of the water directly using spin echo techniques, as had been pioneered by Hahn¹ and Carr and Purcell² and much applied by the group of NMR spectroscopists at Bell Labs, especially by Dave McCall.

I encouraged John to try because I had become interested in spin echo diffusion measurements after I read a note by Don Woessner reporting that the diffusion coefficient of benzene in a rubber stopper was dependent upon the parameters of the experiment, particularly on how long it took to make the measurement.³ His explanation was that for short times, where the diffusion coefficient was larger, the benzene molecules could move more freely than they could for longer diffusion times, where they might meet restrictions among the rubber molecules. The qualitative explanation seemed clear enough but the task of making a quantitative analysis looked like a challenge. Since I was interested in the microscopic details of molecular motion and still fancied myself something of a theoretician, I started trying to understand the problem better. It became clear quickly that while the brute-force analysis of such behavior was probably tractable, it would not be easy, flexible, or insightful. Besides, I was lazy and looking for an easier solution, preferably one that could be presented in closed form rather than as a table of computer output. Remember, in those days, computers were not that fast, did not function interactively, and had poor graphics capabilities. I was too impatient to wait hours or days for the next batch of numbers to come back from the computer lab to decide where I needed to go next. I had had enough of that doing my thesis research on the ILLIAC.

Dave McCall was helpful from the beginning, supplying drawings and photographs of his diffusion apparatus as well as a fistful of reprints describing the work done at Bell Labs, both experimental and theoretical.

John Tanner made good progress implementing the various strategies necessary to measure diffusion by means of a

magnetic field gradient. However, it was clear that, no matter how large a gradient one could make and still use, a larger gradient would look like the solution to the problems at hand. Remember, he was trying to measure ever slower diffusion. But, as the gradient increased, the lines got broader (actually the echoes got narrower) and harder to measure. Meanwhile, I kept working with the equations governing restricted diffusion in a steady magnetic field gradient, filling up a file folder with unfruitful attempts to get an easy solution. The problem was that a diffusive jump had a greater or lesser effect on the echo attenuation depending where it occurred during the experiment, never mind about non-Fickian behavior.

Just before midnight on 1st May, 1963, I made a note in the equipment logbook (I didn't have a laboratory notebook, as such): 'Why not vary G in the time between pulses to accentuate the effect of diffusion without unduly narrowing the echoes? ...' The sketches of the pulse sequence were quite prophetic and both the rudimentary analysis and the suggested circuit for pulsing the gradient were to prove tolerably accurate. I still have this logbook. I left a note (which also still exists) for John Tanner and went home around 1.00 a.m.

John set about implementing the idea, right away. Since he already had a steady gradient set-up, all he needed to try the first experiment was some way to pulse the gradient current. We both set about trying to analyze the experiment to get the relationship between the gradient pattern and the effects of simple Fickian diffusion. John chose a statistical approach, based on the approach of Carr and Purcell.² I chose to obtain a differential equation to solve, based on the analysis of steady gradients and diffusion first developed by Torrey⁴ and given in Abragam.⁵ I got a useful solution first, which John was then able to check by a totally different approach. It was clear that we had a way to extend the measurement to much smaller values of the diffusion coefficient than had been possible before. It was John, with his much more pictorial, statistical approach, who first noted that the definition of the diffusion time was clear and easily interpretable if the gradient pulses were short compared with the time between them. Thus, suddenly both John's and my problem were solved by the same experiment. As it turned out, John never went back to his original problem. He was too busy working out the details of the pulsed field gradient, spin echo (PFGSE) experiment.⁶ He and I worked independently on the theory of restricted diffusion, each preferring his different approach to the diffusive process.^{7,8}

The theory I worked out, following and extending Torrey,⁴ also predicted that flow would not attenuate the echo but, rather, cause it to shift phase. In common with most pulsed NMR spectrometers of the time, mine was not phase-coherent, so I could not test or apply that aspect of the theory. Later, Ken Packer did.⁹ I had a low-resolution magnet and FT NMR had not yet been widely implemented, so the tantalizing possibility of studying diffusion in a multicomponent system had to wait for James and McDonald.¹⁰

John Tanner received his Ph.D. in 1965 and continued for years developing and improving the PFGSE experiment. He first suggested and implemented the use of the stimulated echo to extend the practical diffusion time. He also proposed a number of ADRF and ARRF experiments to achieve the same thing, but I do not think they were ever tried. By about 1970 I had pretty much lost interest in measuring diffusion since the

Monsanto Company, where I was then working, could not see its practical usefulness and did not encourage me to continue. For the first time since then, I now have a student tooling up to make PFGSE measurements.

What were the real antecedents of the PFGSE measurement? I am not sure. In the course of readying the first manuscript for publication, we were made aware of a recent article by McCall, Douglass, and Anderson,¹¹ the Bell group, that suggested that varying the gradient (an 'alternating field gradient . . . ' in the language of the paper) could extend the measurement to smaller diffusion coefficients by reducing the power requirements of the pulse transmitter. I had spoken to Dave McCall about a year prior to my first logbook entry about problems of diffusion measurements, in general. Later, having seen the journal statement, I asked Dave whether we had discussed this point earlier. He thought we had, but if so it did not register at the time and I had no conscious memory of it when I made my logbook entry. He is probably right; it would not have been the first good idea he directed my way. It was a reviewer of our first article⁶ who pointed out that we were not the first to study spin echoes in the presence of magnetic field gradient pulses. In a 1955 article titled: 'Spin Echo Serial Storage Memory,' Anderson, Garwin, Hahn, Horton, Tucker, and Walker, at IBM-Watson Laboratories, described an expanded use of multiple stimulated echoes in a magnetic field gradient turned on and off during the experiment, as convenient.¹² They were not interested in diffusion, indeed they would have preferred it not to be present, but rather in a computer memory device. I have no excuse for being ignorant of any article of Erwin Hahn's; in those days, however, the American Physical Society recommended crediting multiple-author papers alphabetically, and he was buried in the middle of the list.

With the equipment available at the time, the first PFGSE measurements were extraordinarily difficult to perform with useful precision. I might have continued working with the method at Monsanto if better instrumentation had been available. As it was, a new generation of instrumentation had to come along before the measurements could achieve their full potential. So, the experiment may classify as one just slightly ahead of its time. Not so early that it had to be reinvented, but one that required a period in limbo before it re-emerged as a 'standard method.' When I presented a seminar, on CPMAS,

not PFGSE, to a group of Alex Pines' graduate students in 1986, it was reported to me afterward that one of the students, obviously well up on the older NMR literature, asked if 'the guy who did the pulsed field gradient diffusion work in the 1960's' was my father.

The source of these thoughts is John Tanner's notebooks and thesis; my logbook; the various publications cited, especially the dates thereon; a conversation with Dave McCall about 30 years ago; a conversation with John Tanner about two years ago; and, least reliable of the lot, my own recollections.

Sternhell, S.: Development of NMR Spectroscopy as a Structural Tool

S. Sternhell

University of Sydney, Sydney, New South Wales, Australia

The importance of NMR is not principally intrinsic: it is due to its applications. Thus nuclear magnetic resonance spectroscopy is almost certainly the most widely used technique for the elucidation of the structures of organic and organometallic molecules, and is a powerful method for the determination of the composition of mixtures of compounds. In addition, it has direct applications to the study of molecular dynamics and to problems which lie principally in the fields of biology and medicine rather than chemistry, as well as a growing applicability in the analysis of solid state samples. More recently NMR imaging, closely related to NMR spectroscopy, has become established as a powerful clinical technique. NMR spectrometers are ubiquitous in chemical laboratories and represent the greatest single investment in chemical instrumentation, while NMR spectroscopy and its applications form integral parts of chemistry courses at all universities.

Perhaps the most striking feature of the development of NMR spectroscopy has been its speed: the phenomenon of NMR was discovered in 1945, the phenomenon of chemical shift, and hence the first major application, is generally dated¹ to 1950 and any number of active practitioners of chemistry, this author included, vividly remember the dark ages pre-NMR.

The development of NMR took place along a number of parallel but interrelated lines. Thus, one can talk of developments in NMR physics, in NMR instrumentation, in NMR techniques, and in the interpretation of NMR spectra. A constant feature apparent from the beginning of the massive application of NMR to chemistry in the late 1950s to the present has been the gap between sophisticated and unsophisticated users, the latter outnumbering the former by about two orders of magnitude. To my knowledge, this has been a most unusual, if not unique, phenomenon in a major scientific field; in fact, a subcategory of authors has been active over the whole period trying to make the mysteries of NMR accessible to the uninitiated. This brief review of the development of NMR will be written from this perspective, i.e. it will not be concerned with the allocation of priorities but with the appearance of developments which had a major impact on applications of NMR.

NMR PHYSICS

From the point of view of applications, the major developments in NMR physics took place early and were codified by Pople, Schneider, and Bernstein,² and Abragam.³ These two monographs found their way onto the shelves of numerous users of NMR where they were much puzzled over, but rarely understood by most users of the method.

In the early days of NMR the principal problem in interpreting NMR spectra—which were almost entirely what we now term 1D, ¹H spectra—was *the analysis of the hyperfine structure*, which to this day is misnamed as ‘the analysis of high-resolution NMR spectra’. The underlying principles of the extraction of NMR parameters from spectra are straightforward, were codified early,^{2,4} and an excellent text pitched at just the correct level was written by R. J. Abraham⁵ in 1971. However, to this day and in spite of relevant advances in instrumentation, computation, and techniques (see below), the analysis of high-resolution NMR spectra baffles most users.

A second physics-related problem concerned the *time dimension* of NMR spectroscopy. While research into dynamic NMR⁶ has normally been the preserve of a relatively small number of specialists who had no problems in understanding and applying the relevant concepts, serious physics-related problems for general users emerged with the development of pulsed NMR in the late 1960s. In particular, in spite of the incorporation of such material into standard lecture courses, even the current crop of young researchers in organic and inorganic chemistry often have trouble in understanding the mechanisms of relaxation and the whole concept of spin gymnastics, in spite of the fact that the underlying principles are well established.

NMR INSTRUMENTATION AND TECHNIQUES

The development of NMR *instrumentation* has been dominated by changing magnet technology, microelectronics, and computing, the revolution in the latter fields coinciding with the development of the NMR method. On the one hand, we have seen the unending quest for higher field strengths driven by the requirements of dispersion, sensitivity, and simplification, and on the other the development of the electronics, particularly since the replacement of the CW techniques by pulsed methods. The results have been astonishing, the most routinely used instruments outperforming those which had been the best available about five years before. On several occasions users (myself included) were trapped into declaring the technology ‘mature’, only to be proven wrong by another quantum leap. Nevertheless, I will predict again that unless a completely new form of superconducting magnet appears, the 400 MHz machine will become the standard nonspecialist’s instrument. The firm which will make the cheapest user-friendly version of this instrument should reap considerable benefits.

By NMR *techniques*, I understand the spectroscopic and other experimental methods used to acquire NMR information. For the first few years of commercially available NMR, the commonly usable techniques were simply CW (field sweep or frequency sweep) 1D spectra, but the introduction of spin decoupling made an impact as early as 1962. Interestingly, the signal-averaging techniques, such as Varian’s CAT 1024, failed to take hold although they addressed the then principal limitation of NMR spectroscopy, viz. low sensitivity. The two major basic developments in instrumentation and technique became widely known in the late 1960s and early 1970s: I am referring, of course, to the appearance of superconducting magnets and the switch from CW to FT spectroscopy. These developments increased the sensitivity of NMR to a spectacular extent, opened the door to multinuclear MR, and

made ^{13}C NMR (including a little later the edited variety) routinely accessible, thus roughly doubling the utility of the method. At the same time, the interpretability of ^1H NMR spectra became easier due to the superior dispersing power of high-field instruments. It is interesting how this development has overshadowed the introduction of shift reagents in 1966⁷ which, in principle, helped with this problem as well as giving other useful information at a negligible cost. It is also interesting that the potentially revolutionary nuclear Overhauser effect had to wait for FT spectroscopy for full acceptance.

Two-dimensional NMR, which became routinely accepted during the 1980s,⁸ enlarged the utility of NMR by making the determination of connectivity much easier (COSY) and accessing heteronuclear correlations (particularly ^1H , ^{13}C) and NOE values. The development of the INADEQUATE technique, which has the potential of defining the complete linkage of the carbon skeleton in a single experiment, has not yet become a part of the routine armory of the chemist, mainly due to the limitations in sensitivity, but there are no inherent reasons why it should not do so. In fact, a problem now faced by the nonspecialist is to decide which of the numerous techniques⁸ to apply!

INTERPRETATION OF NMR SPECTRA

Instrumentation and techniques enable us to extract NMR parameters (e.g., chemical shifts, coupling constants, ^1H , ^{13}C correlations, etc.) from NMR spectra, but to obtain information about molecular structure it is necessary to correlate such data with structural features. Thus a ^{13}C signal for a quaternary carbon near δ 200 ppm indicates the presence of a ketone or aldehyde, a three proton singlet near δ 4 ppm suggests a methoxyl group, and vicinal $^3J(\text{H,H})$ values obey a well-known (if more complex than is generally realized) Karplus relationship. Unlike the developments in NMR instrumentation and techniques, the appearance of NMR data proceeded incrementally rather than by a series of revolutionary leaps. The first useful compilation accompanying a general text⁹ was produced by Jackman in 1959, but not many analogous works have appeared since. The reasons are not difficult to find: the literature contains an astronomical amount of data, but as soon as one attempts to produce useful compilations one finds that all sorts of obvious data are hard to find or even missing, and need to be established experimentally.

The whole exercise is a tedious labour of love because, with the possible exception of ^{13}C chemical shifts, little of the search is simply mechanical. This explains why few useful

major compilations and correlations are available and why old favorites¹⁰ are not only found on the shelves of working chemists, but are still much consulted although getting quite elderly.

Strange, John H.: Echoes of the Past

John H. Strange

University of Kent, Canterbury, UK

One of the first papers I read as a new graduate student was the excellent explanation by Pake¹ of the formation of nuclear magnetic resonance spin echoes originally discovered and published by Erwin Hahn in 1950. The fascination of manipulating those minute nuclear magnets to rotate, and then recover lost phase coherence after perhaps more than a million complete rotations under their Larmor precession, fired my early enthusiasm for NMR. I had arrived in London in 1960 to start work on a Ph.D. under the supervision of J. G. Powles, who had recently set up the first pulsed NMR spectrometer in the UK. However, I had to await his 'slow passage return' via the Mediterranean camp sites from an early AMPERE meeting in Pisa and hence I had started some reading on my own. On his return I discovered that he had presented a paper² on work with Tony Hartland that described echo amplitude modulation by J coupling interactions in liquids. In those days, pulsed NMR tended to be the domain of the physicist and high-resolution work as a means of chemical analysis was carried out by the chemists using continuous wave methods. Technological development seemed to be aimed at increasing spectral resolution which was usually limited by magnet technology and spectrometer stability. It had occurred to Jack Powles, while sitting in a London traffic jam on his way home from the laboratory, that a (Carr–Purcell) train of echoes should cancel inhomogeneity and also chemical shift and the Fourier transform of the echo amplitudes would reveal J spectra from which J couplings could be determined with great accuracy and data collected rapidly. Following the demonstration of the idea,² it became my job to develop and explore this approach.

At this time no commercial pulsed NMR machine was available—we built our own—and the digital computer was in its infancy. My first Fourier transforms were evaluated numerically by using a hand-operated mechanical calculator and it took most of 1 day to transform a set of transient data (obtained in 1 second) to obtain one spectrum. One of our earlier successes was the measurement of the variation of J coupling in acetaldehyde as a function of temperature to an accuracy of 0.01 Hz. We were able to interpret this in terms of internal molecular reorientations. Our work was presented at a Faraday Discussion in Oxford in 1962 and I can still remember John Waugh, who had received a preprint of our results, announcing after our paper had been read, that he had checked our results with his (latest and best) CW Varian spectrometer using the conventional method and (.pause) confirmed our observations!

Echo amplitude modulation was relatively straightforward to interpret for the first-order spectra of simple molecules but even then we found that the chemical shift could not be ignored. A full theoretical analysis of the echo amplitude modulation became rapidly intractable for more complex molecules although the additional variable parameter—the

echo spacing—offered opportunities for the study of dynamical processes such as the rate of chemical exchange.³ Perhaps it was because we had such poor homogeneity in our magnets that we were rather obsessed with overcoming this, using echoes, and hence overlooked the great advantages to be obtained from the (in retrospect) obvious and simpler approach of Fourier transformation of the free induction decay. This awaited the seminal works of Richard Ernst on Fourier transform NMR (see Ernst's Historical Sketch) which also stimulated commercial manufacture of the pulsed spectrometer, exploited the growing power of the computer, and opened up time-domain experiments, including relaxation work, to scientists in all the disciplines and not just those with DIY (do it yourself) inclinations.

While I was engaged on the echo amplitude modulation work, I shared an old 5 kG (0.5 T) permanent magnet with another graduate student, Peter Mansfield. He was at this time developing a unique high-power pulsed spectrometer designed to allow pulsed NMR to be used for solid materials. I became aware of Peter's observation of unexpected signals obtained while setting up his new spectrometer. We always used a 90° – τ – 90° pulse sequence to set up our spectrometers and, of course, when τ is much shorter than T_1 but longer than T_2 and the 90° pulses are set accurately, the signal following the second 90° should be zero. This signal was seen to fluctuate unexpectedly for solids if τ was set to be less than T_2 . It should be mentioned that our spectrometer technology of that time usually employed pulsed oscillators so that the radiofrequency pulses were incoherent. The fluctuations, it transpired, were due to the phase fluctuation between the pulses. Peter Mansfield was able to control the phase with remarkable ingenuity using improvised precision time delays from a (very new and expensive) Tektronix oscilloscope timebase. The principle of solid echo formation was established.⁴ The echo forms by a partial recovery of phase loss arising from the dipole–dipole interaction between nuclei in a rigid lattice following a 90° – τ – 90° sequence where the second pulse is phase-shifted by 90° from the first. Again I became involved in spin echo work, but now in solids. Jack Powles and I were able to demonstrate the general principles of solid echo formation and effectively produce zero time-resolution for observation of free induction decays in solids.⁵ This early work on solid echoes laid the foundation for multipulse line-narrowing techniques (MREV8 and WAHUA for example) for high-resolution spectroscopy of solids developed primarily by Peter Mansfield, John Waugh, and their collaborators in the late 1960s. Fourier transformation of the multiple echo-like signals yielded the otherwise obscured chemical shift and scalar interactions. These methods have continued in their development, requiring sophisticated calculation of spin dynamics. New sequences based on those 'solid echo' developments (see *Line Narrowing Methods in Solids and Imaging Techniques for Solids and Quasi-Solids*) as well as multiple-echo methods in liquids (see for example *Echo-Planar Imaging*) are still appearing today in the techniques applied to magnetic resonance imaging. Spin-echo methods in multidimensional magnetic resonance techniques are now of considerable importance in structural analytical methods of molecules in the liquid state. The work of Jack Powles and his students of the early 1960s in London reechoes still in the contemporary methods of magnetic resonance.

Current interests: diffusion and imaging in solids and porous media.

Sutcliffe, Leslie H.: A Career in Magnetic Resonance Spectroscopy

Leslie H. Sutcliffe

University of Surrey, Guildford, UK

My first researches in spectroscopy were in the area of vacuum-ultraviolet spectroscopy with Donald Walsh. At Liverpool University, I used spectroscopic methods to study mechanisms of inorganic oxidation–reduction reactions in solution. There was a lack of a really powerful physical technique for such studies and Charles McDowell suggested that I should consider magnetic resonance methods—which I had never heard of! Being used to constructing our own spectrometers, we set about building an ESR spectrometer. Unfortunately, the sensitivity proved to be far too low for the research projects we had in mind and we got no acceptable results until the arrival of our Varian ESR spectrometer in 1960. While the ESR spectrometer was being built, news came of the availability of a commercial NMR spectrometer. Luckily, Cecil Bawn, the then head of the Donnan Chemistry Laboratories, was anxious to create a first-rate research department, hence he was very keen to acquire such an instrument for my use. The first three Varian HR-40 spectrometers arrived in the UK in 1957, one for Liverpool, one for Cambridge, and one for ICI, Blackley. For me it was the start of parallel researches in NMR and ESR that have given me immense pleasure and satisfaction—and they still continue to do so, but ironically magnetic resonance didn't help much with my reaction kinetics projects! Joe Lee (an optical spectroscopist from Walsh's group) joined me as a postdoctoral fellow to help get the NMR researches underway: our first successes were with the ^{19}F resonance spectroscopy of organic fluorine compounds. This came about from a very fruitful collaboration with the research group at ICI, Widnes, who provided us with a large number of interesting compounds. They had found that IR and mass spectroscopy were not particularly helpful in establishing the structure of such compounds. In one study we were able to prove the structure of the anaesthetic halothane within minutes to Charles Suckling. The power of NMR for solving problems was also demonstrated when Joe Chatt wanted to confirm that he had made the first platinum hydride complex. We were able to prove quickly that the proton NMR spectrum was consistent with his ideas and we also evaluated $J(\text{Pt}, \text{H})$ from the ^{195}Pt satellites. Our instrumentation improved continuously as Varian converted our spectrometer first to HR-60 and then to HA-60. This was to be the only new NMR spectrometer to which I have had free access.

In 1959, Jim Feeney became one of my first research students in magnetic resonance—the beginning of a long line of talented co-workers to join my group working in this area. Our researches on fluorine compounds came to the attention of Ken Musgrave at Durham and we started to cooperate with him (Dick Chambers also came on the scene later) on some fascinating fluorinated alicyclics. There must still be many interesting new fluorine compounds synthesized by other fluorine groups that cry out for detailed investigation.

Jim Emsley joined the group as a postdoctoral fellow after gaining NMR experience with John Smith at Leeds on a homebuilt NMR spectrometer; later on, Ken Musgrave recruited him and he moved to Durham. It was clear to me that there was a great need for a book on the chemical aspects of NMR (no Bernstein, Pople, and Schneider as yet!) and so I began to write one. By 1960 it was obvious that the subject was beginning to expand rapidly, hence both Jim Feeney and Jim Emsley were persuaded to become co-authors. When 'High Resolution Nuclear Magnetic Spectroscopy' was published in 1965 by Pergamon Press, after some publisher's delay, it was already out of date. Rather than attempt to revise the book, I suggested that we start the series *Progress in Nuclear Magnetic Resonance Spectroscopy* and the first volume appeared in 1966. As a result of the astounding and continuing expansion of NMR, it continues to flourish.

In the early days of NMR, I was associated with two significant developments. The 'tau' scale for proton chemical shifts was adopted enthusiastically by organic chemists but, apart from the scale being illogical, there were problems as other nuclei began to be studied. The 'delta' scale was more suitable, but people were referring to upfield shifts as being positive but, from our extensive experience on spectral analysis, it was pointed out that these should be negative as frequency (energy) decreases with field increase. When I was chairman of the independent British NMR discussion group, affiliation with the Chemical Society (now the Royal Society of Chemistry) was an attractive proposition but there was no suitable division for the group: after some discussion the Interdisciplinary Division was created to accommodate our group (and other groups later).

Most of my NMR work has been concerned with chemical and structural applications, perhaps the most useful results being (i) the demonstration that F,F 'through-space' coupling can be enormous—I believe that Gordon Tiddy and I hold the world record of 196 Hz; (ii) that the sign of such couplings is always positive; (iii) that these coupling constants can be used to determine F,F distances; and (iv) the provision of rules for assigning fluorine chemical shifts in cyclic compounds. For most of our work, we required a full and precise analysis of spin systems and we encountered many frustrations with early computational methods.

There have been some instrumental developments in my laboratory. After pulse methods had virtually taken over from CW in the 1970s, there still remained the problem of examining a small region of a spectrum at the highest possible resolution. With Peter Craven and Bill McIlwaine, a CW correlation technique was developed that could be controlled by a PC: the system could bring new life to old CW spectrometers. This work is unpublished but it is interesting to note that the method is attracting attention at the present time and that Hitachi market a spectrometer based on an approach similar to ours.

In 1986, I joined forces with Duncan Gillies to enable us to further our interest in molecular dynamics, using mainly ^{13}C T_1 and NOE NMR relaxation measurements and asymmetric line broadening in the ESR spectra of spin probes. Duncan's foresight and great persistence has provided our laboratory with one of the few high-pressure multinuclear MR facilities in the world. We are examining a series of compounds some of which contain normal alkyl chains and others cyclohexyl rings—these are models for low- and high-traction

lubricants, respectively. We have shown that long hydrocarbon chains have the same dynamic behavior whether they are in lubricants, surfactant micelles, or biological membranes. In addition, we are developing radiofrequency ESR spectroscopic and imaging techniques. There is a niche for the latter (EMRI) for areas of research in which NMR imaging is not sufficiently sensitive or is inappropriate. It is pleasing to find that instrumental methods similar to those for CW NMR are directly applicable to ESR radiofrequency spectroscopy.

Current research specialties: high-pressure NMR, NMR, and ESR of free radicals, ESR spectroscopy and imaging at radiofrequencies with applications to diffusion in foods, rocks, and plants.

Sykes, Brian D.: When Biochemistry became Chemistry

Brian D. Sykes

University of Alberta, Edmonton, Alberta, Canada

After an introduction to NMR with J. S. Martin at the University of Alberta, and a non-NMR summer (unfortunately) with W. G. Schneider (of the Pople, Schneider, and Bernstein book fame) at the NRC labs in Ottawa, I joined J. D. Baldeschwieler's group at Stanford University in 1965. John's group was very active in several diverse fields including NMR studies using quadrupolar nuclei to follow the rotational dynamics of molecules, halide-ion probe NMR studies of biological macromolecules, and the development of ion cyclotron resonance spectroscopy (ICR); the latter was based in large part on magnetic resonance concepts such as double resonance which John's group had worked on previously. John set me to work on ideas he had for a solution version of the heteronuclear Hartmann–Hahn experiments (after the Ph.D. thesis of F. M. Lurie, University of Illinois, 1963), which was a very good idea and eventually came to light in the experiments of Pines, Gibby, and Waugh, and the HOHAHA correlation experiments which are so popular today. However, I was inexperienced and only barely made the experiment work, mostly due to difficulties in building spectrometer components for the 56 MHz pulsed NMR spectrometer in John's lab at that time. After another false start, I remember John suggesting that I convert to ICR, but I resisted this. I then spent months working through the fascinating paper by Meiboom on NMR studies of exchange in H₂O.¹ This paper, along with the paper by Swift and Connick,² set the stage for my involvement with NMR relaxation and chemical exchange processes, and especially with the use of NMR to study the exchange of ligands with biological macromolecules.

I had never intended to work with biological molecules in any way, or to become a biochemist. But biochemistry became chemistry with the determination of the three-dimensional structures of the first protein and enzyme. For me, the 1966 *Scientific American* article on lysozyme³ had the greatest impact. When I then saw the initial lysozyme NMR papers of Thomas⁴ and of Raftery et al.,⁵ and the chymotrypsin paper of Richards and co-workers,⁶ I recognized that the reported differential broadening of substrate resonances in fast exchange between their free and bound states was not always due to different correlation times, but proportional to the bound chemical shift differences squared and therefore caused by chemical exchange. From that point on I became permanently involved in the field of biological NMR. I developed a sensitive adiabatic half-passage $T_{1\rho}$ method for measuring relaxation times, used this to study the binding of substrates to lysozyme and chymotrypsin, began to label substrates with ¹⁹F to study their interactions with biological macromolecules, and got involved, along with Paul Schmidt, with large proteins such as ATCase.

Several memories strike me about that time. Firstly, fields were so unstable that NMR linewidths were different

if measured sweeping upfield or downfield. Secondly, in theoretical developments we never considered that nuclei could be outside the extreme narrowing limit. Thirdly, as graduate students we visited Varian in Palo Alto, and I remember Richard Ernst discussing his latest proposals for NMR signal-to-noise enhancement, but I did not listen closely enough to realize that I could have jumped on the FT bandwagon many years earlier than I did.

I then moved to the Chemistry Department at Harvard University in 1969 and was very fortunate to pick up a group of excellent graduate students. We became involved in a wide variety of biological systems, using in turn, a variety of NMR approaches. Amongst other things, we used ¹³C NMR and ¹H NOE methods to determine the structure of retinal analogs, followed *J* coupling constants to measure distortion of lysozyme substrates, used fluorine-labeled amino acids to probe the structure and dynamics of large proteins such as alkaline phosphatase, developed the theoretical foundations of NOE measurements and relaxation in these systems, used ³¹P NMR to study the mechanism of alkaline phosphatase, discovered slowly exchanging amide protons and slowly flipping aromatic residues in the bovine pancreatic trypsin inhibitor (BPTI), worked on stopped flow NMR to follow enzyme kinetics, used lanthanides for structural tools, and worked on eliminating the water resonance (like everybody else). We called our method WEFT, since other methods like DEFT had appeared, unfortunately contributing to the relentless drive that is so popular in NMR to add to the acronym alphabet soup. Looking back at how things turned out, I am reminded of the 1974 International Conference on Magnetic Resonance in Biological Systems meeting in Kanterstag, Switzerland, where Grayson Synder and I presented our BPTI results alongside of the very similar results of Wagner and Wüthrich. It was clear this was going to become a very popular protein. Consequently I decided, when I moved to Alberta in 1975, that I would move on to larger and more 'biologically relevant' proteins, while Wüthrich and co-workers began the development along with Ernst of 2D NMR and of the sequential assignment methods that were to eventually turn us all into structural people.

Temussi, Piero Andrea: NMR Studies of Flexible Bioactive Molecules

Piero Andrea Temussi

Università di Napoli Federico II, Napoli, Italy

My relationship with NMR is closely linked to the motivations that led me to study chemistry: I was fascinated by the mystery of the structure–activity relationships of drugs and wanted to find a means of determining them experimentally. The way to do this, in the end, was through NMR but it was a long and winding road.

The prerequisite for anybody who wished to become an NMR spectroscopist was to go to the United States. I was no exception and decided to go to the lab of one of the NMR pioneers, Herbert S. Gutowsky. I learned something about NMR and chemical exchange, enough to export NMR knowledge back to Italy, but was still looking for tools to study bioactive molecules.

Even after real structural work on proteins became a reality, it was very difficult to get the means to study proteins in detail, at least in Naples, in terms of the availability of high-field spectrometers and dedicated computers. I resorted to small peptides that presented little difficulty in their spectra but a big challenge in terms of interpretation. The occasion was furnished by a sweet peptide: aspartame. Its structural study is typical of the difficulties involved in the study of small flexible molecules in solution. It was impossible to detect any diagnostic NOE; all conformational information was derived from coupling constants and energy calculations. Nevertheless, the NMR study of aspartame provided the hint for a complete model of the sweet receptor¹ and encouraged me in the study of more complex bioactive peptides.

The main problem posed by flexibility is that there is not a single well-defined structure in solution. This is what led me to investigate environmental constraints. The first approach was to choose a 'structured' solvent medium. Many peptide hormones interact with active sites of receptors that are hydrophobic pockets of membrane proteins. Normally, peptides are completely insoluble in apolar solvents but, in the case of enkephalin amides, complexation with crown ethers of their N-terminal cationic sites allow their solubilization in organic solvents. Crown ethers act as part of an artificial receptor site² and the NMR spectrum resembles that of fully structured cyclic peptides.

A much more general approach is represented by cryoprotective mixtures at low temperature. Initially we were looking for a means of increasing NOEs in small molecules. The obvious answer was to increase the viscosity of the solution. In the case of peptides we wanted solvents that could be considered biocompatible, and in this context, we have experimented with a series of mixed solvent systems, the so-called cryoprotective mixtures. These mixtures, composed of water and an organic solvent in various proportions, had previously been used in crystallographic and biochemical studies on several proteins. Their most distinctive feature is that, at low temperatures, they are isoelectric with water at room temperature. Cryoprotective mixtures are also characterized by a nearly complete

biocompatibility, e.g. all enzymes tested in cryoprotective mixtures function normally and, generally, with kinetics identical to that in water. In addition, they have high viscosities whose precise value can be modulated by the proper choice of solvent composition and/or temperature.

Their use for peptides or other flexible molecules was originally proposed as a means of overcoming the technical problem of negligible NOEs exhibited by small molecules, because of the condition $\omega^2\tau_c^2 \approx 1$ generally encountered at high fields. At that time ROESY was just being introduced, but our instrumentation was not compatible with it. That is why we termed our approach with cryomixtures as the 'poor people's ROESY'. Using this system, we succeeded in measuring the first NOEs of enkephalin, a very flexible bioactive peptide.³

Subsequently, when ROESY became available to everybody (including us), I realized that the use of cryomixtures had further advantages. High viscosity does not simply increase the size of NOEs by increasing τ_c , as predicted by the theory of microviscosity, but acts as a conformational sieve by limiting the flexibility of small peptides.⁴ Thus, conformations detected in cryoprotective mixtures are generally different from those found in pure solvents of low viscosity. This method of studying flexible bioactive molecules is now of general application and may be considered as a first step in structure–activity studies of any peptide hormone.

The most important aspect of the use of highly viscous media in the study of peptide hormones is the simulation of one crucial feature of their biological environment. Neuropeptides exert their biological action at synapses. They are excreted by specialized vesicles of the presynapse and reach membrane receptors located on the postsynaptic membrane by crossing a cleft of 100–500 Å occupied by the intersynaptic fluid. One important physicochemical feature of cytoplasm is viscosity. The typical viscosities of cytoplasm range from 5–30 cP,⁵ and it has been postulated⁶ that they play an important role in cell communication processes. It is probable that the intersynaptic fluid has a viscosity higher than cytoplasm, because of the ordering effect of membrane heads and of unstirred layer phenomena. It seems reasonable to postulate, therefore, that the viscosity of this fluid also contributes, in addition to the membrane catalysis,⁷ in allowing the entropic barrier to the transition state of peptide–receptor interaction to be overcome by selecting ordered conformations prior to receptor interaction.

The Development of NMR

Edwin D. Becker and Cherie L. Fisk

National Institutes of Health, Bethesda, MD, USA

C. L. Khetrapal

Indian Institute of Science, Bangalore, India

THE ORIGINS OF NMR

The history of NMR, like any history, has no real beginning. Every development, every discovery can be traced back to antecedents that provided basic theory or applicable technology ready to be exploited. To the extent that the origin of NMR can be identified, however, it surely must lie in the development of the concept of spin as a quantum mechanical entity. We begin our story of the evolution of NMR with a review of electron spin and nuclear spin and of the experiments that verified these fundamental concepts. We discuss the investigations in which nuclear magnetic resonance was first observed in molecular beams, then describe the discovery of NMR in bulk materials 50 years ago.

As NMR phenomena and theory were better understood, it became apparent that the technique could be applied in many fields, and concurrent developments occurred in physics, chemistry, biology, and other disciplines. New concepts in NMR have continually been discovered, and major improvements in instrumentation and technology have fostered ever-expanding roles for NMR. To present this multifaceted account in a reasonably coherent manner, we have divided our story into 18 sections, each in approximately chronological order internally. We make frequent references to the interplay of the various aspects of NMR development.

This chronology serves only as a summary of the developments that are chronicled in much more detail in the 200 articles that follow. Many of the leading figures in the development of NMR have presented largely autobiographical accounts of many aspects of NMR. In our overall chronology we provide frequent references to these articles.

Electron Spin and Nuclear Spin

Physicists in the 1920s were elated with the success of quantum theory in explaining a number of phenomena that had defied understanding within the framework of classical mechanics. In particular, the existence of discrete lines in the absorption and emission spectra of atoms, and the spacings of those lines, could be understood conceptually and in some instances explained quantitatively. As spectral resolution improved, however, and spectra of additional atomic species were studied, some disturbing observations were made. Closely spaced doublet spectral lines were found that could not be explained by the old (Bohr) quantum theory. In 1925, Uhlenbeck and Goudsmit¹ introduced the concept of a spinning electron, with resultant angular momentum

(quantized as $\frac{1}{2}\hbar$) and a magnetic dipole moment arising from the spinning electrical charge.

In 1926, the Schrödinger/Heisenberg formulation of quantum mechanics replaced the old quantum theory and provided a more satisfactory basis for understanding many phenomena, but in its initial form it also failed to account for the doublets. In 1927, Pauli² and Darwin³ developed a theoretical framework for grafting the concept of electron spin onto the new quantum mechanics. The next year, Dirac's formulation of relativistic quantum mechanics showed that a fourth quantum number was required, and this turned out to be the electron spin with its quantum of $\frac{1}{2}\hbar$. While the classical picture of a spinning charged particle is useful, the theory treats the angular momentum and magnetic moment simply as constants of Nature.

Meanwhile, anomalies in the heat capacity of hydrogen led Dennison⁴ to propose that the proton has a spin with an angular momentum of $\frac{1}{2}\hbar$. Molecular hydrogen, H_2 , would then consist of two proton spins oriented parallel to each other (*ortho*) or antiparallel (*para*). The proton-spin concept completely accounted for the heat capacity results. In fact, in 1924, Pauli had already suggested the possibility of a nuclear spin to account for the hyperfine spectral structure.⁵ This proposal came before the idea of electron spin had been formulated and was based on the widespread misconception that the nucleus consists of protons and electrons. (The neutron was not discovered until 1932.) Nevertheless, Pauli is usually regarded as the initial proponent of an intrinsic nuclear spin.

Atomic and Molecular Beams

In 1921, Stern and Gerlach^{6,7} had carried out their famous experiment in which a beam of silver atoms was formed in a high vacuum and passed through a magnetic field in an experimental arrangement shown schematically in Figure 1. This was before the development of the idea of an intrinsic spin for either electrons or nuclei, but during the period that the old quantum theory broke with classical mechanics to postulate quantized *orbital* angular momentum for electrons. Thus, the Stern–Gerlach experiment was designed to observe either a continuous range of deflection of the silver atoms in the inhomogeneous magnetic field or a discrete number of atomic beams from the quantized orbital electron motion. The result clearly confirmed the basic tenets of the quantum theory.

With the concept of intrinsic nuclear and electron spin contributing to magnetic moments, Stern and his collaborators made major improvements to the sensitivity of their beam apparatus in order to be able to detect the much smaller

Figure 1 Schematic representation of the experimental arrangement for the Stern–Gerlach experiment

Figure 2 Schematic representation of the apparatus for Rabi's molecular beam experiments. Magnets A and B are electric wires that produce inhomogeneous magnetic fields. The third magnet C, also made of electric wires, was introduced to measure signs of magnetic moments. Later, Magnet C was changed to a homogeneous field for resonance studies

nuclear magnetic moments. In 1933, they were able to measure the effect of nuclear spin by the deflection of a beam of hydrogen molecules, for which there is no contribution to the magnetic moment from electron orbital angular momentum.^{8,9} Thus the nuclear magnetic moment of the proton (and in a separate experiment of the deuteron from D_2 molecules) could be determined. However, accuracy was not high, since molecules with different velocities move in somewhat different trajectories, and the detected spots are smeared out.

During the early 1930s, Rabi's laboratory at Columbia University became a major center for atomic and molecular beam studies. Breit and Rabi examined the interactions between nuclear and electron magnetic moments in atomic beams and devised methods to overcome the problem of velocity distribution. For hydrogen, however, it was necessary to modify the apparatus (Figure 2) by introducing a second inhomogeneous magnetic field that would refocus the beam to produce a spot corresponding to the location of an undeflected beam. From the magnitudes of the magnetic field gradients in magnets A and B, together with other parameters, the magnitudes of the 1H and 2H nuclear magnetic moments were determined with greatly improved accuracy. By introducing a third inhomogeneous magnetic field between A and B, they caused nonadiabatic transitions that could reveal the sign of the magnetic moment.¹⁰ In 1936, they found that the signs of both moments were positive and determined the values $\mu_H = 2.85 (\pm 5\%)$ and $\mu_D = 0.85 (\pm 3.5\%)$.¹¹ [These values are to within 1–2% of the current values, $\mu_H = 2.792\,68$ and $\mu_D = 0.857\,387$.] However, still greater precision was needed to permit interpretation of the moments in terms of nuclear structure. A breakthrough in the precision of measurement was soon to come with the introduction of *resonance* methods, a subject to which we shall return.

Nuclear Magnetism in Bulk Materials

While molecular beam studies were directed toward precise measurements of nuclear magnetic properties in isolated atoms or molecules, other efforts were underway to measure the effect of nuclear magnetic phenomena in solids. Simple theoretical considerations of the presence of nuclear magnetic moments show that there must be a Boltzmann distribution of the moments among the quantized states and a resultant equilibrium nuclear paramagnetic susceptibility. The problem in detecting this quantity directly is that it is very small relative to the diamagnetic susceptibility from electrons in the sample. However, in 1937, Lasarew and Schubnikow¹² demonstrated

the nuclear susceptibility in solid hydrogen at 2 K, where the Boltzmann distribution enhanced its contribution.

Meanwhile, C. J. Gorter, a leading Dutch physicist who had demonstrated paramagnetic relaxation from electrons, attempted in 1936 to observe the effects of nuclear paramagnetism. His approach was to use a *resonance* property of the nuclear spins when they are placed in a magnetic field B_0 . Gorter knew from the Larmor relation

$$\nu_0 = (\gamma/2\pi)B_0 \quad (1)$$

that at this resonance frequency a magnetic dipole transition should occur if an alternating (radiofrequency) field B_1 is applied perpendicular to B_0 . Gorter used a static field in which B_0 could be varied up to 1.4 T, and applied a 20 MHz field with B_1 as large as 1 mT. His plan was to detect the heat produced by resonant absorption in the sample by using a sensitive calorimetric method that he had successfully employed in studies of electron paramagnetic relaxation. He looked for 1H resonance in $KAl(SO_4)_2 \cdot 12H_2O$ and for 7Li in LiF, both pure crystalline materials, at 14–20 K. Gorter expected a temperature rise of $0.3^\circ C \text{ min}^{-1}$, which was about 100 times as large as his limit of detection, *provided* that the Boltzmann equilibrium was established and maintained. Unfortunately, Gorter observed no heat absorption from the resonant process and concluded that a long spin–lattice relaxation time caused the spin system to be partially saturated when radiofrequency (rf) energy was absorbed. In retrospect, it appears that Gorter's choice of samples that he described as 'very pure' prevented relaxation by paramagnetic impurities, and his decision to work at very low temperature exacerbated the problem of long T_1 values. While his experiment was unsuccessful, Gorter did publish the result.¹³ His main contribution may have been to focus attention on the potential utility of resonance methods.

Nuclear Magnetic Resonance in a Molecular Beam

Rabi and his colleagues had refined beam methods, and in his 1937 theoretical paper entitled 'Space Quantization in a Gyating Magnetic Field' Rabi treated a field that was oscillatory in time as a simplification to the actual case of molecules moving through fields which varied in space rather than time.¹⁰ As Norman Ramsey points out in his historical sketch (*Ramsey, Norman F.: Origins of Magnetic Resonance*), this paper provides formulas that were later directly applicable to resonant behavior, but the theoretical transition probability was written in a form that obscured its resonant nature and the subsequent averaging over velocities eliminated sharp resonances. In fact, the word 'resonance' does not appear in the paper. According to Ramsey, Rabi did discuss with colleagues the possibility of using oscillatory magnetic fields, but no experiments were done or even planned for some months.

From more detailed accounts (*van der Waals, J. H.: Gorter's Footprints on the Trail That Led to Magnetic Resonance*, and *Torrey, Henry C.: Precursive and Early Work on NMR*), it is clear that the stimulus for attempting such resonance studies came from a visit by Gorter to Rabi's laboratory in September 1937. Rabi's apparatus at that time was configured so as to be able to measure the sign of the magnetic moment in one experiment and its magnitude in a

separate experiment. As discussed in Section 1.2, a third inhomogeneous magnet was inserted for the sign determination, as shown in Figure 2, and nonadiabatic transitions between nuclear spin states occurred as the molecules passed through this field. Gorter asked the crucial question why transitions could not be induced more efficiently by resonant absorption of rf energy in a homogeneous magnetic field placed between the A and B magnets of Figure 2. Gorter apparently realized that in Rabi's beam method such rf absorption would cause interchange of the spin orientations in both components of the beam, so the effect of the resonance absorption would be additive in reducing the signal from the focused beam on its target. In his own unsuccessful experiment, on the other hand, only the difference between populations was effective in energy absorption from the rf field.

While Rabi had evidently already recognized the value of a resonance experiment, Gorter's suggestion prompted immediate action. Two days after his visit, modifications to the apparatus had begun to test the resonance approach. John Rigden's historical sketch (*Rigden, John S.: Rabi's Resonance Method*) describes in detail the background of the molecular beam work in Rabi's laboratory and depicts the tension and drama as Rabi and his co-workers steadily increased the magnet current while a fixed 3.5 MHz rf was applied to a coil in the magnet. At a current of 116 A the signal from the detector abruptly dropped, then regained its initial value at higher current. The predicted resonance had been observed! In January 1938, Rabi, Zacharias, Millman, and Kusch submitted to the *Physical Review* a short Letter¹⁴, reproduced in its entirety in Figure 3. The signal from LiCl shown in Figure 3 is really the first reported nuclear magnetic resonance. Rabi et al. correctly noted that 'The method is capable of very high precision and extension to a large number and variety of nuclei'. In 1944, Rabi was awarded the Nobel Prize for his extensive and important work on molecular beams, especially the resonance method.

Rabi's publication in 1938 refers to Gorter's earlier unsuccessful attempt and acknowledges his visit, but does not point out his role in suggesting the experiment. Gorter's reaction to this publication was restrained:¹⁵

I cannot deny that I felt some pride, mixed with the feeling that my contribution was somewhat undervalued though my advice was acknowledged in the Letter.

As Torrey says succinctly in his historical sketch (*Torrey, Henry C.: Precursive and Early Work on NMR*):

No one has ever doubted that Rabi richly deserved the Nobel Prize he was awarded in 1944, but Gorter clearly deserved a noble prize for the good grace and lack of rancor with which he accepted the undervaluation of his contribution to Rabi's success as well as the near misses in his own quest of NMR . . .

With the new resonance method, Rabi and his colleagues investigated a number of molecules, including paramagnetic species, in which the interaction between nuclear and electron spins had to be considered. They also extended the method to H₂, D₂, and HD, where magnetic dipole, spin-rotation, and nuclear quadrupole interactions are important.¹⁶ In the paper reporting the details of this work, the term *radiofrequency spectroscopy* was introduced. The resonant beam methods provided excellent precision since the lines were sharp and radiofrequencies could be measured quite accurately. However, the determination of the absolute values of the

nuclear moments of ¹H and ²H was limited to about 0.1% because of limitations in the accuracy of the magnetic field measurement.

A method similar in principle to the molecular beam resonance technique was used by Bloch and Alvarez to measure the magnetic moment of the neutron.¹⁷ In this experiment the deflecting and refocusing magnetic fields of Figure 2 were replaced by two magnetized iron plates, which served to polarize and analyze the neutron beam. Between the two sets of plates a homogeneous magnet and rf coil permitted resonance transitions, as in the Rabi method. This method was apparently conceived by Bloch before he had heard of Rabi's successful resonance experiments, but was carried out in 1939. Bloch and Alvarez showed that the moments of the neutron and proton add to give that of the deuteron within 1%, but limitations in the measurement of the magnetic field prevented a more precise comparison. Eventually it was a search for a better method of measuring magnetic fields that led Bloch to try to observe NMR in bulk materials.

The World War II Years

With the outbreak of World War II, most basic research ceased or at least was relegated to secondary status. Rabi moved to Cambridge, MA, where he became Associate Director of the Radiation Laboratory at the Massachusetts Institute of Technology (MIT). He was responsible for the development of microwave sources for use in radar systems. Among the young physicists working in this laboratory was Edward Purcell, later to make his mark on NMR. Bloch worked in the Manhattan Project on studies of the properties of uranium isotopes, then also moved to Cambridge to work at Harvard University's Radar Research Laboratory on radar countermeasures. While the war certainly delayed further research into NMR, the experience of Bloch, Purcell, and many others in radar research or in the practical operation of military radar had an immense positive impact on the speed with which instrumentation for NMR was developed after the war.

Although the war prevented the usual Nobel Prize ceremonies in Stockholm, the Nobel Committee in Physics was not oblivious to the fundamental contributions made by molecular beam research. In 1944, the 1943 Nobel Prize in Physics was awarded to Otto Stern (Figure 4) (who had moved to the United States in 1933)—'for his contribution to the development of the molecular-ray method and his discovery of the magnetic moment of the proton'. At the same time, the 1944 Nobel Prize was awarded to I. I. Rabi (Figure 5) 'for his resonance method for recording the magnetic properties of atomic nuclei'. The awards were presented in New York rather than Stockholm.

Surprisingly, in war-torn Europe, two experiments of note to magnetic resonance were carried out. In the Netherlands, Gorter, encouraged by Rabi's successful resonance experiments, decided to try again to observe NMR in bulk materials. He and his colleague L. J. F. Broer replaced the calorimeter as a means of detection by relying instead on the expected anomalous dispersion of the magnetic susceptibility in the vicinity of a resonance, as indicated in Figure 6. With considerable difficulty, they assembled suitable apparatus and in 1942 carried out the experiment at the Kamerlingh Ohnes Laboratory in Leiden. They used crystalline LiCl and KF samples,

A New Method of Measuring Nuclear Magnetic Moment*

It is the purpose of this note to describe an experiment in which nuclear magnetic moment is measured very directly. The method is capable of very high precision and extension to a large number and variety of nuclei.

Consider a beam of molecules, such as LiCl, traversing a magnetic field which is sufficiently strong to decouple completely the nuclear spins from one another and from the molecular rotation. If a small oscillating magnetic field is applied at right angles to a much larger constant field, a re-orientation of the nuclear spin and magnetic moment with respect to the constant field will occur when the frequency of the oscillating field is close to the Larmor frequency of precession of the particular angular momentum vector in question. This precession frequency is given by

$$\nu = \mu H / h i = g(i) \mu_0 H / h, \quad (1)$$

To apply these ideas a beam of molecules in a $^1\Sigma$ state (no electronic moment) is spread by an inhomogeneous magnetic field and refocused onto a detector by a subsequent field, somewhat as in the experiment of Kellogg, Rabi and Zacharias.¹ As in that experiment the re-orienting field is placed in the region between the two magnets. The homogeneous field is produced by an electromagnet capable of supplying uniform fields up to 6000 gauss in a gap 6 mm wide and 5 cm long. In the gap is placed a loop of wire in the form of a hairpin (with its axis parallel to the direction of the beam) which is connected to a source of current at radiofrequency to produce the oscillating field at right angles to the steady field. If a re-orientation of a spin occurs in this field, the subsequent conditions in the second deflecting field are no longer correct for refocusing, and the intensity at the detector goes down. The experimental procedure is to vary the homogeneous

field for some given value of the frequency of the oscillating field until the resonance is observed by a drop in intensity at the detector and a subsequent recovery when the resonance value is passed.

The re-orientation process is more accurately described as one in which transitions occur between the various magnetic levels given by the quantum number m_i of the particular angular momentum vector in question. An exact solution for the transition probability was given by Rabi^{2,3} for the case where the variable field rotates rather than oscillates. However, it is more convenient experimentally to use an oscillating field, in which case the transition probability is approximately the same for *weak* oscillating fields *near* the resonance frequency, except that ϑ is replaced by $\vartheta/2$ in Eq. (13). With this replacement and with passage to the limit of weak oscillating fields, the formula becomes for the case of $i = \frac{1}{2}$

$$P(\frac{1}{2}, -\frac{1}{2}) = \frac{\vartheta^2}{(1-q)^2 + q\vartheta^2} \sin^2 \{ \pi \tau [(1-q)^2 + q\vartheta^2]^{1/2} \}, \quad (2)$$

where ϑ is $\frac{1}{2}$ the ratio of the oscillating field to the steady field, q is the ratio of the Larmor frequency of Eq. (1) to the frequency ν of the oscillating field. The denominator of the expression is the familiar resonance denominator. The formula is generalized to any spin i by formula (17).³

In the theory of this experiment, t , in Eq. (2), is replaced by L/v , where L is the length of the oscillating region of the field, and v is the molecular velocity. $P(\frac{1}{2}, -\frac{1}{2})$ must then be averaged over the Maxwellian distribution of velocities. However, the first term is not affected by the velocity distribution if t is long enough for many oscillations to take place. The average value of the $\sin^2$ term over the velocity distribution is approximately $\frac{1}{2}$.

To produce deflections of the weakly magnetic molecules sufficient to make the apparatus sensitive to this effect, the beam is made 245 cm long; the first deflecting field is 52 cm in length and the second 100 cm.

We have tried this experiment with LiCl and observed the resonance peaks of Li and Cl. The effects are very striking and the resonances sharp (Fig. 1). A full account of this experiment, together with the values of the nuclear moments, will be published when the homogeneous field is recalibrated.

³ J. Gorter, *Physica* 9, 995 (1936). We are very much indebted to Dr. Gorter who, when visiting our laboratory in September 1937, drew our attention to his stimulating experiments in which he attempted to measure nuclear moments by observing the rise in temperature of solids placed in a constant magnetic field on which an oscillating field was superimposed. Dr. F. Bloch has independently worked out similar ideas but for another purpose (unpublished).

FIG. 1. Curve showing refocused beam intensity at various values of the homogeneous field. One ampere corresponds to about 18.4 gauss. The frequency of the oscillating field was held constant at 3.518×10^4 cycles per second.

once again choosing molecules that would minimize magnetic dipolar interactions in the hope that this would lead to relatively narrow lines. Again they worked at low temperature (liquid hydrogen and liquid helium) to maximize the magnitude of the static nuclear magnetic susceptibility. However, once again, they observed no effect on passing through the expected resonance.¹⁸ They concluded that T_1 for their samples must have been more than 1000 s (a good estimate, since Bloembergen much later measured T_1 as 600 s at 2.1 K with Gorter's LiCl sample). Unfortunately, they did not (perhaps, under wartime conditions, could not) try other samples at higher temperatures.

The second relevant experiment was the discovery of electron spin resonance by E. K. Zavoisky at Kazan, Russia, in 1944–45. Physicists at the time were aware of the possibility of observing such a resonance, and a substantial body of knowledge existed on electronic interactions and the mechanism of paramagnetic relaxation, whereas detailed mechanisms of nuclear relaxation were unknown. However, according to the account by *Kochelaev, Boris I.: Discovery of Electron Spin Resonance*, Zavoisky attempted first to detect NMR in 1941. He used a sample of water to which paramagnetic ions were added to shorten the completely unknown relaxation time, and a flowing sample was used in some experiments, presumably to reduce saturation from the rf field. Zavoisky was inspired by Rabi's resonance studies in molecular beams, but he was also aware of Gorter's unsuccessful attempt in 1936 to detect NMR. Kochelaev reports that Zavoisky apparently observed an NMR signal in May or June 1941, but it was not reproducible. Further efforts

Figure 5 I. I. Rabi. (Reproduced by permission of the Nobel Foundation)

Figure 6 Theoretical absorption and dispersion plots of magnetic susceptibility.¹⁸ (Reproduced by permission of Elsevier Science Publishers)

were cut short by the beginning of hostilities in Russia and the move of several laboratories from Moscow to the more remote Kazan, thereby displacing Zavoisky's laboratory. It is thought that inadequacies in the electronics and poor magnetic field homogeneity prevented any successful experiment.

When Zavoisky was able to resume some research in 1943, he turned his attention to the study of paramagnetic relaxation but retained an interest in NMR. However, he apparently

carried out no successful experiments in NMR. He then moved on to trying to detect electron resonance in both solids and solutions of paramagnetic salts. After he had obtained some dubious results in a solenoid at very low magnetic fields, he built equipment to work in the range of 1 GHz and obtained signals that were reported in his thesis in October 1944. In January 1945, he repeated the measurements at the Institute of Physical Problems in Moscow and published a short paper,¹⁹ which is generally accepted as the first reported observation of ESR.

NMR IN BULK MATERIALS

With the end of World War II in sight, many American scientists began to think of post-war research opportunities. In 1944, Rabi and Norman Ramsey spent an evening together in Cambridge, MA, discussing possible experiments. They considered an effort to look for NMR absorption in bulk materials and were excited by their favorable signal-to-noise calculations. However, they recalled Gorter's failure for unknown reasons and decided to defer such experiments in favor of other research (which ultimately provided important advances in relativistic quantum electrodynamics) (see *Ramsey, Norman F.: Origins of Magnetic Resonance*). Purcell, who was at that time not aware of Gorter's experiments, also began thinking about such NMR experiments. Meanwhile, Bloch became interested in the possibility of developing an NMR method using bulk materials as a simple means for accurately measuring magnetic fields, so he could make a more precise comparison of the magnetic moments of the neutron, proton, and deuteron in molecular beams. According to J. H. Van Vleck,²⁰ in whose group Bloch worked at Harvard, Bloch was thinking about possible relaxation processes that would overcome the problems that had defeated Gorter, but without success. Although Purcell and Bloch worked only a few miles from each other during this period, they did not meet (except perhaps at a social function) and did not visit each other's laboratories, partially at least because of security restrictions.

Plans and Preparations at Stanford

Bloch left the Radar Research Laboratory (RRL) at Harvard in 1945 to return to Stanford and re-established a research program. With the experience in rf techniques that he had acquired at the RRL, he believed that the transitions of nuclear magnetic moments in a resonance experiment could be detected in a simpler way than by measuring the deflection of a molecular beam. Bloch reasoned that the macroscopic nuclear magnetization that gives rise to the static nuclear magnetic susceptibility would be tipped away from its equilibrium position along the z axis (Figure 7) by the resonance absorption of energy from an rf field. The resulting magnetization, precessing about the applied magnetic field B_0 would induce an electrical signal in a coil placed along the x or y axis. According to Martin Packard's fascinating account of this early work (*Packard, Martin E.: Nuclear Induction at Stanford and the Transition to Varian*) the idea for the method came to Bloch during a concert while he was still at the RRL, and he discussed the feasibility with W. W. Hansen, another Stanford physicist who was at the same laboratory. Back

Figure 7 Schematic representation of a macroscopic nuclear magnetization M precessing about the magnetic field along the z axis after being tipped away from its equilibrium position along z by an rf field H_1

at Stanford, Bloch formed a collaboration with Hansen, an electronics expert, and recruited Martin Packard as a graduate student. In late September they began to build and assemble apparatus, a process that was to take about three months.

The Discovery at MIT/Harvard

Meanwhile, at the MIT Radiation Laboratory, several staff members had been asked to stay on for up to a year, even though the wartime research effort had ended, to contribute to a series of books that would chronicle the advances made in the classified research. Among them were Edward M. Purcell, leader of a group in fundamental research, Henry C. Torrey, who had led a group on crystal rectifiers, and Robert V. Pound, who had been responsible for crystal mixers. One day in September, 1945, these three met for lunch and Purcell raised the question of detecting the transition between nuclear magnetic energy levels using rf methods. Torrey, who had worked in Rabi's laboratory, recalled that such experiments had been discussed at Columbia but ruled out as not likely to work. However, that evening Torrey calculated the expected magnitude of the signal, provided equilibrium could be attained in the magnetic field, and concluded that the measurement should be feasible. On hearing that result, Purcell proposed trying the experiment.

As described in Bob Pound's lucid account (*Pound, Robert V.: Early Days in NMR*) the project was undertaken as a sideline, since all three were working full time (and that included Saturday mornings) on the Radiation Laboratory books. Purcell looked unsuccessfully for a suitable magnet at MIT but was able to arrange to use a large magnet at Harvard that had previously been employed for cosmic ray research. Thus it came about that the first NMR signals eventually were obtained at Harvard, even though all three authors were employed by MIT, as indicated in their first paper. Purcell designed new pole caps to improve the homogeneity of the magnetic field and had them constructed in the Harvard physics shop, while Pound and Torrey worked at MIT on the design and construction of an electronic bridge circuit. Because they were so engrossed with microwave technology, they elected to build a cavity resonant at 30 MHz rather than use more conventional electronic components. The cavity was enormous

by later NMR standards, about 12 cm in diameter and 8 cm long, and could accommodate an 850 mL sample.

As preparations for the experiment moved ahead, the collaborators' principal concern related to the totally unknown spin–lattice relaxation time. Some estimates based on first-order interactions between nuclear spins and lattice phonons suggested that the relaxation time could be as long as 10^6 years! However, Torrey estimated that second-order processes might reduce the relaxation time at room temperature to as little as one hour. Purcell, Torrey, and Pound were initially unaware of Gorter's somewhat similar unsuccessful experiment. When Rabi learned of Purcell's plans and told him of Gorter's work, Purcell was disappointed but felt that their planned approach was feasible and had progressed to the point that the experiment should be conducted. Rabi also expressed to Torrey his concern that magnetic dipolar interactions in the solid would broaden lines beyond detection.

Preparations were completed for the first attempt on Thursday, December 13. They filled the cavity with about 1 kg of paraffin wax, carefully balanced the bridge circuit, and spent the evening (in fact, until 4 a.m.) looking for an unbalance in the bridge that would indicate passage through resonance. The frequency of their apparatus was fixed at 30 MHz, so scanning took the form of varying the magnetic field in the region where resonance was expected. From molecular beam data, they expected resonance at about 7400 G. With their relatively crude magnetic field measurement capability, they expected resonance to occur at a magnet current of about 73 A. They scanned from about 65 to 80 A to allow for a possible 10% error in calibration, but could see no signal. Finally, they shut down the magnet and decided to try again on the next Saturday afternoon. They suspected that they may not have reached equilibrium, so Purcell agreed to turn on the magnet about 7 a.m. and let the sample equilibrate for several hours.

The frustrations of Thursday night were repeated on Saturday afternoon. The galvanometer remained in its steady-state position as the magnetic field was scanned. They thought about ways of enhancing sensitivity, such as the use of magnetic field modulation and lock-in detection. Before ending their session, however, one of them suggested raising the magnetic field to its maximum value (ca. 100 A current) and reducing the field slowly to zero. At 83 A the meter kicked exactly as they had hoped. There was the resonance! They verified the signal and found the resonance field to be completely reproducible. They removed the sample from the magnet and replaced it. The signal was just as large, demonstrating that the relaxation time was orders of magnitude shorter than expected.

Why did Purcell, Torrey, and Pound almost miss seeing resonance? They had not realized the extent to which the iron in the large gap magnet saturated. Their field measurement actually was within 2% of the correct value and they had allowed what seemed to be a more than adequate $\pm 5\%$ variation in the magnet current, but because of iron saturation it took 15% more current to reach the correct field strength. As Pound says, 'How embarrassing it would have been if we had not accidentally discovered our error.' They did discover the error, however, and for the first time NMR was observed in a bulk material, not only in a molecular beam.

The Letter reporting this discovery (reproduced in Figure 8) was received by the *Physical Review* on December 24, 1945, and published in January, 1946.²¹ Later, in his Nobel

Prize lecture in 1952 (see *Purcell, Edward M.: Research in Nuclear Magnetism*), Purcell was to say:

I remember in the winter of our first experiments, just seven years ago, looking on snow with new eyes. There the snow lay around my doorstep—great heaps of protons quietly precessing in the Earth's magnetic field. To see the world for a moment as something rich and strange is the private reward of many a discovery. But I'm afraid it has little bearing on the sober question we must, as physicists, ask ourselves: what can we learn from all this about the structure of matter?

The answer, 50 years after this initial observation, goes far beyond anything anticipated at that time and forms the basis of this Encyclopedia.

Success at Stanford

During the course of their work, Purcell, Torrey, and Pound had become aware of the similar project at Stanford, and they learned that Rabi described their efforts to Bloch in a visit to Stanford in December. But even without this information the work at Stanford was proceeding, and by early January, 1946, Bloch, Hansen, and Packard were ready to try their experiment. (As mentioned in Packard's historical sketch, *Packard, Martin E.: Nuclear Induction at Stanford and the Transition to Varian*, the experiment might have been done a week or so earlier if graduate student Packard had not chosen to visit his parents in Oregon over Christmas.) Their apparatus was set up in the cyclotron laboratory at Stanford, a leaky, unheated area in the basement of the original quadrangle. In fact, the magnet that they used, a small lecture demonstration magnet with a 4–5 inch gap, was connected in series with the nearby cyclotron magnet and used that magnet's power supply and regulator. Their electronic setup was considerably different from that used by Purcell, Torrey, and Pound. Rather than looking for a bridge unbalance as energy was absorbed, Bloch, Hansen, and Packard placed the sample in a brass box (called the 'probe') along with two orthogonal electrical coils, one of which was used to excite the sample with rf while the second was used to pick up the nuclear induction signal as the magnetization precessed after the resonant absorption. A novel arrangement of 'paddles' was used to steer magnetic flux between the two coils and permit selection of dispersion or absorption mode. Sensitivity was enhanced by using magnetic field modulation to shift the signal away from dc and avoid low-frequency ($1/f$) noise.

Bloch had assumed that the spin–lattice relaxation time might be very long, perhaps days, while transverse relaxation from magnetic dipole–dipole interactions between nearby protons might occur rapidly and broaden the signal. Because of this concern about a long T_1 value, they allowed their sample of liquid water to come to equilibrium in a fringe field of the cyclotron magnet for 24 h before attempting any measurement. Moreover, the rf field was maintained at a few gauss to minimize saturation of the sample. They adjusted the magnetic field to a value that would provide resonance at their 7.76 MHz excitation frequency. However, the measurement of the field was just as inaccurate as that at Harvard, since the classical methods used were the same.

The experience at Stanford was almost a repeat of that at Harvard. After two hours of fruitless attempts to observe a signal on the oscilloscope screen, the three investigators

Resonance Absorption by Nuclear Magnetic Moments in a Solid

E. M. PURCELL, H. C. TORREY, AND R. V. POUND*
*Radiation Laboratory, Massachusetts Institute of Technology,
 Cambridge, Massachusetts*
 December 24, 1945

IN the well-known magnetic resonance method for the determination of nuclear magnetic moments by molecular beams,¹ transitions are induced between energy levels which correspond to different orientations of the nuclear spin in a strong, constant, applied magnetic field. We have observed the absorption of radiofrequency energy, due to such transitions, in a *solid* material (paraffin) containing protons. In this case there are two levels, the separation of which corresponds to a frequency, ν , near 30 megacycles/sec., at the magnetic field strength, H , used in our experiment, according to the relation $h\nu = 2\mu H$. Although the difference in population of the two levels is very slight at room temperature ($h\nu/kT \sim 10^{-5}$), the number of nuclei taking part is so large that a measurable effect is to be expected providing thermal equilibrium can be established. If one assumes that the only local fields of importance are caused by the moments of neighboring nuclei, one can show that the imaginary part of the magnetic permeability, at resonance, should be of the order $h\nu/kT$. The absence from this expression of the nuclear moment and the internuclear distance is explained by the fact that the influence of these factors upon absorption cross section per nucleus and density of nuclei is just cancelled by their influence on the width of the observed resonance.

A crucial question concerns the time required for the establishment of thermal equilibrium between spins and lattice. A difference in the populations of the two levels is a prerequisite for the observed absorption, because of the relation between absorption and stimulated emission. Moreover, unless the relaxation time is very short the absorption of energy from the radiofrequency field will equalize the population of the levels, more or less rapidly, depending on the strength of this r-f field. In the expectation of a long relaxation time (several hours), we chose to use so weak an oscillating field that the absorption would persist for hours regardless of the relaxation time, once thermal equilibrium had been established.

A resonant cavity was made in the form of a short section of coaxial line loaded heavily by the capacity of an end plate. It was adjusted to resonate at about 30 mc/sec. Input and output coupling loops were provided. The inductive part of the cavity was filled with 850 cm³ of paraffin, which remained at room temperature throughout the experiment. The resonator was placed in the gap of the large cosmic-ray magnet in the Research Laboratory of Physics, at Harvard. Radiofrequency power was introduced into the cavity at a level of about 10^{-11} watts. The radiofrequency magnetic field in the cavity was everywhere perpendicular to the steady field. The cavity output was balanced in phase and amplitude against another portion of the signal generator output. Any residual signal, after amplification and detection, was indicated by a microammeter.

With the r-f circuit balanced the strong magnetic field

was slowly varied. An extremely sharp resonance absorption was observed. At the peak of the absorption the deflection of the output meter was roughly 20 times the magnitude of fluctuations due to noise, frequency, instability, etc. The absorption reduced the cavity output by 0.4 percent, and as the loaded Q of the cavity was 670, the imaginary part of the permeability of paraffin, at resonance, was about $3 \cdot 10^{-6}$, as predicted.

Resonance occurred at a field of 7100 oersteds, and a frequency of 29.8 mc/sec., according to our rather rough calibration. We did not attempt a precise calibration of the field and frequency, and the value of the proton magnetic moment inferred from the above numbers, 2.75 nuclear magnetons, agrees satisfactorily with the accepted value, 2.7896, established by the molecular beam method.

The full width of the resonance, at half value, is about 10 oersteds, which may be caused in part by inhomogeneities in the magnetic field which were known to be of this order. The width due to local fields from neighboring nuclei had been estimated at about 4 oersteds.

The relaxation time was apparently shorter than the time ($\sim$ one minute) required to bring the field up to the resonance value. The types of spin-lattice coupling suggested by I. Waller² fail by a factor of several hundred to account for a time so short.

The method can be refined in both sensitivity and precision. In particular, it appears feasible to increase the sensitivity by a factor of several hundred through a change in detection technique. The method seems applicable to the precise measurement of magnetic moments (strictly, gyromagnetic ratios) of most moderately abundant nuclei. It provides a way to investigate the interesting question of spin-lattice coupling. Incidentally, as the apparatus required is rather simple, the method should be useful for standardization of magnetic fields. An extension of the method in which the r-f field has a rotating component should make possible the determination of the sign of the moment.

The effect here described was sought previously by Gorter and Broer, whose experiments are described in a paper³ which came to our attention during the course of this work. Actually, they looked for dispersion, rather than absorption, in LiCl and KF. Their negative result is perhaps to be attributed to one of the following circumstances: (a) the applied oscillating field may have been so strong, and the relaxation time so long, that thermal equilibrium was destroyed before the effect could be observed—(b) at the low temperatures required to make the change in permeability easily detectable by their procedure, the relaxation time may have been so long that thermal equilibrium was never established.

Nuclear Induction

F. BLOCH, W. W. HANSEN, AND MARTIN PACKARD
Stanford University, Stanford University, California
 January 29, 1946

THE nuclear magnetic moments of a substance in a constant magnetic field would be expected to give rise to a small paramagnetic polarization, provided thermal equilibrium be established, or at least approached. By superposing on the constant field (z direction) an oscillating magnetic field in the x direction, the polarization, originally parallel to the constant field, will be forced to precess about that field with a latitude which decreases as the frequency of the oscillating field approaches the Larmor frequency. For frequencies near this magnetic resonance frequency one can, therefore, expect an oscillating induced voltage in a pick-up coil with axis parallel to the y direction. Simple calculation shows that with reasonable apparatus dimensions the signal power from the pick-up coil will be substantially larger than the thermal noise power in a practicable frequency band.

We have established this new effect using water at room temperature and observing the signal induced in a coil by the rotation of the proton moments. In some of the experiments paramagnetic catalysts were used to accelerate the establishment of thermal equilibrium.

By use of conventional radio techniques the induced voltage was observed to produce the expected pattern on an oscillograph screen. Measurements at two frequencies ν showed the effect to occur at values H of the z field such that the ratio H/ν had the same value. Within our experimental error this ratio agreed with the g value for protons, as determined by Kellogg, Rabi, Ramsey, and Zacharias.¹

We have thought of various investigations in which this effect can be used fruitfully. A detailed account will be published in the near future.

¹ J. M. B. Kellogg, I. I. Rabi, N. F. Ramsey, and J. R. Zacharias, *Phys. Rev.* **56**, 738 (1939).

Figure 9 The first report of nuclear induction.²² (Reproduced by permission of the American Physical Society)

decided to increase the field well above what was expected to be needed and allow it to drift downward at a rate determined by the time constant of the cyclotron magnet. Packard was watching the screen and saw a weak signal flit across. Nuclear induction was born!

During the next few days, Bloch was able to explain much of what had been observed. He understood in general that the rapid tumbling of the water molecules must be responsible for the much shorter relaxation time, but he did not anticipate the description of 'motional narrowing' later developed by Bloembergen. He did explain the observation of the signal with positive and negative lobes as resulting from the scanning conditions; he named it 'adiabatic rapid passage'. The short Letter describing this work (reproduced in its entirety in Figure 9) was received by the *Physical Review* on January 29, 1946, about a month after the Purcell, Torrey, and Pound submission, and was published in February.²² Later the Nobel Committee recognized the two discoveries as independent and essentially concurrent. Bloch and Purcell shared the Nobel Prize in Physics in 1952 'for their development of new

Figure 10 Felix Bloch. (Reproduced by permission of the Nobel Foundation)

methods for nuclear magnetic precision measurements and discoveries in connection therewith'. Bloch's Nobel lecture (*Bloch, Felix: The Principle of Nuclear Induction*) includes a concise summary of much of the history of the molecular beam era, as well as a good discussion of the concept of nuclear induction.

One Discovery or Two?

It was not immediately obvious that *nuclear magnetic resonance* and *nuclear induction* measured the same phenomenon. The language in which the initial papers were couched and the theoretical approaches of the two groups somewhat obscured the underlying physics. Moreover, in the initial work the Stanford group reported the dispersion mode, while the MIT group studied absorption. Bloch (Figure 10) has mentioned that, at his first meeting with Purcell (Figure 11), the two had some difficulty communicating in detail because of their different terminology and techniques. However, they, and the broader physics community, soon realized that these two methods probed the same basic phenomena. Purcell's approach was more conventional in terms of treating transitions between quantized energy levels, as was commonly done for molecular beam studies and for all other branches of spectroscopy. Such an approach would prove essential later in understanding many important NMR phenomena. Bloch's treatment of the expectation values of quantum mechanical properties led to a classical picture that was to be the principal method for explaining time-dependent phenomena and for introducing the idea of phase coherence,

Figure 11 Edward Purcell. (Reproduced by permission of the Nobel Foundation)

a concept that is crucial for understanding many aspects of transient NMR experiments.

The experimental methods used in the two laboratories were also quite different. The Stanford group used the novel crossed-coil arrangement mentioned above. In the early days of NMR research, when the magnetic moments of various nuclei were being measured, this geometric arrangement could be adapted to permit the determination of the sign, as well as the magnitude, of the magnetic moment by driving both coils in quadrature. However, in normal operation, with the orthogonal arrangement of the transmitter and receiver coils, ideally there would be no signal appearing in the receiver coil directly from the transmitter, a critical factor in permitting the weak induced voltage to be measured. Since this was long before the advent of phase-sensitive detectors, a phase reference was obtained by deliberately introducing some 'leakage' between the two coils with the flux-steering paddles invented by Hansen. This whole crossed-coil probe arrangement was commercialized and formed the basis of several generations of NMR spectrometers, giving way to a single coil only after the widespread use of pulse methods permitted separation of transmitter and receiver functions in time, rather than space.

As we have pointed out, the MIT apparatus initially used a large cavity reminiscent of microwave methodology. Prior to the first experiment, this cavity with its very large amount of sample was viewed as an advantage in providing a large signal and in being resistant to saturation by the imposed radiofrequency field. When the magnitude of the signal and the shortness of the relaxation times were determined, the MIT workers replaced the cavity with a more conventional single rf

coil that enclosed a small sample. Field modulation was added to reduce noise. Detection was still done with a bridge method, a necessity in order to avoid submerging the small absorption signal under the large amplitude from the transmitter. The single-coil arrangement continued for many years to be used in many academic NMR laboratories because of its simple probe design. The rf apparatus was soon improved, particularly by the introduction of the regenerative, or controlled marginally oscillating, detector, commonly called the 'Pound Box', which could be frequency swept.

As often happens in science, the names of the two methods remained in dispute long after there was agreement on the underlying physics. Bloch insisted for some time on using 'nuclear induction', probably with good justification since his experimental technique did measure the induced signal. According to Warren Proctor (*Proctor, Warren G.: When You and I Were Young, Magnet*),

... one day in the basement he [Bloch] called us all together. ... 'I have had a meeting with Purcell', he explained. 'It is important to be consistent with the nomenclature generally used in physics. It will be known as nuclear magnetic resonance', he concluded.

Early Studies at Stanford

Bloch moved quickly to exploit the new method. Two long papers were submitted to the *Physical Review* in July, 1946, one discussing the theoretical basis of nuclear induction,²³ the other describing the detailed experimental arrangement.²⁴ These papers seem to have had a major effect in popularizing this new concept in the physics community. Also, at the urging of Russell Varian, then a research associate at Stanford, Bloch and Hansen patented nuclear induction and assigned the patent to 'Varian Associates' a company that was not actually incorporated until several months later. In the fall of 1946, Bloch had discussed with Pound the possibility of a joint patent application, but the MIT group was not interested and it would have been difficult to carry out such a joint effort. The MIT work had been published first, but the Stanford project had commenced earlier and the experimental methods used by the two groups were quite different. The Bloch/Hansen patent application was submitted on December 23, 1946, one day short of a year after the Purcell, Torrey, and Pound paper had been received by the journal, thereby ensuring that the requirements of U.S. patent law would be met. Bloch and Hansen were precluded from applying for patents in many foreign countries, which required that the application be filed before publication. We shall return to the consequences of the patent in a later section.

As we pointed out previously, Bloch's impetus for investigating NMR in bulk materials was to develop an accurate method for measuring magnetic fields. His research interests remained focused on nuclear structure, which he viewed as the then central problem in physics. In 1947, Bloch and his co-workers reported precise values for the magnetic moments of ^1H , ^2H , and ^3H , the last of which was carried out at the Los Alamos National Laboratory.^{25,26} In 1948, Bloch, Nicodemus, and Staub reported the quantitative determination of the magnetic moment of the neutron in units of the proton moment,²⁷ a follow-on to Bloch's work on this subject in the 1930s. Emery Rogers, one of Bloch's graduate students, measured

the signs of the proton and neutron moments with the Stanford cyclotron. Meanwhile, a number of graduate students worked with Bloch in measuring magnetic moments for dozens of nuclides, as detailed in Packard's article.

The consequences of the Bloch equations and their solution under different conditions were also examined during this period. In 1948, Jacobsohn and Wangsness²⁸ developed an analytical solution to the equations, which accounted for transient effects such as 'wiggles' that followed passage through resonance.

Early Work at Harvard

Purcell and his colleagues were just as eager as Bloch to exploit their discovery, but they were still constrained by completing their writing project, so things initially moved more slowly in Cambridge than at Stanford. However, in February, 1946, Nicolaas Bloembergen came to Harvard from the Netherlands and decided to do graduate work with Purcell, who was slated to return to his faculty position at Harvard in July. Bloembergen had considerable experience in physics and electronics and was able to advance the research while Purcell and Pound were still busy at MIT. The three collaborated, however, on measurements of ^1H and ^{19}F NMR in the cavity, and Bloembergen began to make improvements in the apparatus. In July, with the writing task completed, Purcell moved to Harvard, along with Pound, who took up his appointment in the Society of Fellows. Torrey departed for Rutgers, where he later pioneered work in transient NMR methods.

Bloembergen, Purcell, and Pound studied a CaF_2 crystal and found the true linewidth and noted its anisotropic character as it was rotated in the magnetic field. They realized, however, that lines in liquids were much narrower (narrower than could be measured with their existing magnet), and that this narrowing resulted from an averaging of magnetic dipolar interactions as the molecules tumbled. This group also devised an experimental study in hydrogen gas, where molecular collisions would modulate the resonance frequency. With increasing pressure, they found an increase in T_1 (from which an increase in T_2 , hence line narrowing, could be inferred) and introduced the term 'pressure narrowing'.²⁹

Meanwhile, Bloembergen devoted an intense three months in the fall of 1946 to developing a theory of relaxation in terms of the effects of random motions. He worked out the spectral densities of the interaction terms between two protons and showed that Fourier components at the Larmor frequency ν_0 and at $2\nu_0$ were responsible for longitudinal relaxation, while terms near zero frequency contributed as well to transverse relaxation. The BPP theory (see *Bloembergen, Nicolaas: My Early Years in NMR, 1946-48*) introduced the idea of 'motional narrowing' and provided the framework for understanding the appearance of NMR spectra. Details of the theory, along with experimental tests in which T_1 was measured as a function of solution viscosity, were published in a preliminary form in *Nature*³⁰ in 1947 and in the famous BPP paper in the *Physical Review*³¹ in 1948. Figure 12 shows the plot that summarized essential features of the theory and provided a guidepost for all future development and understanding of motional effects in NMR.

During this period, Bloembergen also carried out a classic experiment that demonstrated the difference between homogeneous and inhomogeneous broadening. When a truly broad

Figure 12 Schematic representation of the variation of relaxation times with correlation time τ_c .³¹ (Reproduced by permission of the American Physical Society)

line, such as that of CaF_2 , is irradiated with rf power anywhere within the linewidth, the entire line decreases in intensity from saturation. The resonance of water also appeared on an oscilloscope as a broad line, but Bloembergen realized that this broadening arose because nuclei in different parts of the sample had slightly different resonance frequencies in the inhomogeneous magnetic field. He applied rf power at one discrete frequency within the line and observed a decrease in intensity only at that frequency, as saturation 'burned a hole' in the line. This experiment has had considerable application in NMR and, many years later, in optical spectroscopy.

George Pake enrolled in the Harvard physics department in 1946 and became Purcell's second graduate student (perhaps, technically, his first, since Bloembergen was formally enrolled at the University of Leiden). While Bloembergen was busy in the study of nuclear relaxation in liquids, where he observed sharp lines, Pake decided to study solids, where he could observe the natural linewidth of protons in water rigidly bound in a crystal lattice. The essential difference between a liquid and a solid in this context is the lack of molecular motions, resulting in the broadening of the spectral lines in the solid. One of the major factors contributing to such a line broadening arises from the local magnetic fields due to the neighboring magnetic dipoles, which in the liquids are averaged out due to rapid isotropic molecular motions.

For such studies, Pake selected a single crystal of $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ (gypsum) for several reasons: (1) it does not contain any paramagnetic ion and is relatively easily available; (2) it has only protons in the water molecule as the major nuclei with nonvanishing spin and consequently with a magnetic moment; (3) large single crystals exist in Nature; and (4) the crystal structure is well known.

The proton resonance in such a simple crystal showed that the linewidth was strongly dependent upon the crystal orientation in the external magnetic field, with pairs of resonance lines (Pake doublets) arising from two alternative

Figure 13 Upper: Calculated distribution of proton resonance frequencies in $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ for nearest neighbor interactions (broken line) and for a set of Gaussian lineshapes superimposed onto this distribution function (solid line). Lower: Solid curve above recast as a derivative, with experimental points.³² (Reproduced by permission of the American Institute of Physics)

orientations (parallel or antiparallel) of the partner protons. It was shown by Pake that, for each proton, the resonance should occur at a field strength H given by:

$$H = H_0 \pm (3/2)(\mu/r^3)(3 \cos^2 \phi - 1) \quad (2)$$

where H_0 is the applied magnetic field, μ is the proton magnetic moment, r is the pair separation, and ϕ the angle between H_0 and the vector connecting the two nuclei.³²

The theory was extended by Pake to powders, since the spectra for such specimens are the sum of the spectra due to the individual 'single crystals'; the spectral pattern so computed is shown in Figure 13. The figure shows the calculated line-shapes for the proton spectra in polycrystalline gypsum from only the nearest neighbors and from interactions with other neighbors. The experimental results shown in the lower portion of Figure 13 were found to be in general agreement with theory.

From the shape of the line and the separation of the peaks, interproton distances can be computed. NMR thus quickly became a tool for examining *molecular structure*, albeit in rather simple systems. Pake developed a collaboration with Herbert Gutowsky, a graduate student of George Kistiakowsky, in the chemistry department. They developed apparatus to cool samples for NMR study and used their knowledge of magnetic dipolar interactions to interpret linewidth alterations and phase changes in terms of molecular rotations in the solid.³³ Moreover, Pake's work also later became the basis for the use of NMR to study molecules oriented in liquid crystals or by external fields.

Meanwhile, Pound contributed to several projects, especially by utilizing his electronics expertise, but his major interests turned to the effects on NMR spectra of nuclear electric

quadrupole interactions in crystals. After studying a number of light nuclei, such as ^7Li , ^{23}Na , and ^{27}Al , Pound began to look for 'pure' nuclear quadrupole resonance in the absence of a magnetic field, but before he had succeeded, this phenomenon was discovered in a chlorinated ethylene by Dehmelt and Kruger.³⁴

Beginnings of NMR at Other Universities

Although a number of physicists in various parts of the world made forays into NMR very soon after reading the initial papers of the Stanford and Harvard/MIT groups, the early efforts at the University of Illinois were particularly noteworthy and established this institution as one of the early major centers of NMR research. Three separate research efforts came together here within a few years. First, Erwin Hahn entered graduate school in 1946, soon learned about the discoveries of NMR and began work in this field. In 1948, Herbert S. Gutowsky completed his Ph.D. in chemistry at Harvard, where he had done a thesis in infrared spectroscopy but had also studied NMR in solids in collaboration with Pake. He moved to Illinois, where he decided to set up a research program in NMR—one of the first *chemists* to do so. In 1949, Charles P. Slichter arrived in the physics department at Illinois after completing his Ph.D. with Purcell. He had worked primarily in electron resonance rather than NMR, but had gained considerable knowledge of NMR from others in the Harvard laboratory. Each of these three investigators made major contributions to different aspects of NMR, as we shall describe later.

Meanwhile, Pake moved to Washington University and established an NMR laboratory there. He and his students studied quadrupole interactions in ^6Li , the spin of ^9Be , and ESR in free radicals, much of the last in collaboration with Sam Weissman and Jack Townsend. The most famous publication emerging from these early years was not a research paper but two articles written by Pake for the *American Journal of Physics*, in which he gave lucid explanations of the principles of NMR.³⁵ There were no NMR textbooks at that time, and these articles provided the introduction to this field for hundreds (perhaps thousands) of students in physics and chemistry.

As the initial papers on NMR were read throughout the physics community, several investigators with no ties to the Stanford or MIT groups built apparatus and embarked on NMR experiments. One of the most successful of such early efforts was in England, where Bernard Rollin at Oxford University constructed a simple, but elegant, instrument, obtained NMR signals from ^1H and ^{19}F in a variety of solids and liquids, measured their relaxation times, and reported his results in a paper published in November, 1946.³⁶ Rollin and Hutton³⁷ used the same apparatus to measure T_1 and T_2 in liquid and solid hydrogen down to 1 K and later to observe ^2H , ^{27}Al , and ^{63}Cu resonances.³⁸ Further details of Rollin's work, as well as an account of the careers of Raymond Andrew and Rex Richards, are given in the historical sketches (*Andrew, E. Raymond: Spinning the Spins: A Lifetime in NMR*, and *Richards, Rex: Development of NMR in Oxford*).

In 1948–49, E. Raymond Andrew spent a postdoctoral year in Purcell's laboratory, learning about NMR and applying the method to the study of molecular rotations in solid benzenes

and paraffins. On his return to Great Britain (initially at St. Andrews University in Scotland, later at the University of Wales, Bangor), Andrew constructed an NMR spectrometer around a 6000 G permanent magnet and concentrated on the study of NMR in solids. A few years later he discovered magic angle spinning, a subject that we shall cover in detail in a later section. Andrew recognized the need for a book on NMR and in 1954 wrote *Nuclear Magnetic Resonance*.³⁹ Like Pake's articles, this book became an invaluable source of instruction for the physicists and chemists who were increasingly being drawn into NMR.

In 1948, Rex Richards, fresh from a Ph.D. in infrared spectroscopy, began a faculty appointment at Oxford University and decided that the new technique of NMR might have utility in chemistry. He constructed the necessary apparatus and began investigations of NMR linewidths in solids as a function of temperature for studying molecular motions and for elucidating the structure of simple, usually inorganic, compounds in solids. As in other laboratories at that time, the emphasis was on the study of solids because magnet inhomogeneity determined the width of lines in liquids, and no one as yet had any idea that chemical structure could affect the basic resonance frequencies. Later, Richards would make major contributions in chemistry and biology, as we shall see.

Anatole Abragam began a long and distinguished career in physics just after World War II and started to work in NMR in the early 1950s. He established a magnetic resonance laboratory at Saclay, France, in 1955, somewhat later than the other pioneering laboratories discussed above. Nevertheless, his efforts introduced NMR (and electron spin resonance) to most of the French scientific community, and a number of leading NMR scientists from other countries worked there, as Abragam describes in his autobiography.⁴⁰ In Section 4 we discuss some of the innovative work in spin temperature and dynamic nuclear polarization carried out at Saclay. Abragam's historical sketch (*Abragam, Anatole: 'The Bible'*) describes the writing of the widely known monograph *The Principles of Nuclear Magnetism*,⁴¹ published in 1961.

The seeds of NMR research had been planted and were being nourished in an increasing number of laboratories throughout the world. The basic instruments and techniques were still quite primitive, however, and the understanding of NMR theory was still limited. Several additional fundamental discoveries had to be made before NMR began to blossom.

NMR Excitation by Radiofrequency Pulses

Almost all of the early NMR observations were made in the same manner as in the initial experiments at Harvard and Stanford—by sweeping the magnetic field while applying continuous wave (CW) power at a fixed radiofrequency. A few studies (such as those by Pound, mentioned in Section 2.6) used a fixed magnetic field and swept the frequency. But both of these approaches used CW excitation, a means of obtaining NMR spectra that dominated the field for 25 years, as we shall see. Nevertheless, very early in the history of NMR another approach was introduced and developed with very important consequences. This involved the use of short pulses of radiofrequency power applied to excite the nuclear spins. Bloch²³ initially suggested this approach in his paper in 1946:

It is worth while, however, to point out that the observation of nuclear induction should be possible even without any use of the

magnetic resonance. Not only a weak rf field, acting at resonance over very many Larmor periods, can produce an appreciable nuclear change of orientation, but also a strong field pulse, acting over only a few periods. Once the nuclear moments have been turned into an angle with the constant field, they will continue to precess around it and likewise cause a nuclear induction to occur at an instant when the driving pulse has already disappeared. . . . it would observe by induction the free nuclear precession while we have studied the forced precession impressed upon the nuclei by the applied rf field.

Surprisingly, there was no effort at Stanford to try this means of excitation. However, at the University of Illinois, Erwin Hahn had built a CW NMR spectrometer, patterned after the one used at Harvard, but he decided to study the dynamics of spin systems after the application of rf pulses and in particular to measure spin–lattice relaxation times. His Ph.D. thesis, completed in 1949, dealt with adiabatic fast passage effects, spin–lattice relaxation times, and the measurement of transient nutational motions of spins after the application of rf pulses. Hahn published on the use of a pulse to invert the magnetization and permit considerable improvement in the precision of measurement of T_1 for water,⁴² but he soon learned that he had been scooped by Henry Torrey who had independently discovered and explained transient nutations.

After leaving the MIT Radiation Laboratory in 1946, Torrey had initiated a research program in NMR at Rutgers University. He soon developed the picture of magnetization precessing about the applied magnetic field to include consideration of a frame of reference rotating at the applied radiofrequency. As indicated in Figure 14, in the rotating frame the magnetization $\mathbf{M}$ precesses about $\mathbf{H}_{\text{eff}}$ as long as the rf $\mathbf{H}_1$ is being applied. This picture made it clear that in the laboratory frame the motion of $\mathbf{M}$ would be a nutational motion at a frequency $\omega_1 = (1/\gamma)[(\gamma H_1)^2 + (\gamma H_0 - \omega_{\text{rf}})^2]^{1/2}$. Torrey looked for and found the transient signals following the application of an rf pulse, as illustrated in Figure 15.⁴³ This was the first published application of pulses in NMR. Torrey made it clear that this method of *nutational resonance* was different from the free precession predicted by Bloch. This transient nutation technique was developed largely to measure the transverse relaxation time T_2 in the presence of magnetic field inhomogeneities. The method has had some subsequent uses, but it was rapidly overtaken by events back at Illinois.

After receiving his Ph.D., Hahn remained at Illinois for another year to continue exploring the use of pulses with increased rf power and shorter duration, partially as a means of measuring T_1 in the ms range. Torrey had used pulses of 10 ms or longer in order to record a number of nutations during the pulse, but Hahn's short pulses permitted the magnetization to precess freely between pulses, apparently the first experimental application of Bloch's proposal. His T_1 measurements were made with a 60 Hz modulation of the magnetic field. One day during the summer of 1949, as Hahn describes it (*Hahn, Erwin L.: Pulsed NMR—A Personal History*), 'the weird signal appeared'. He had been experimenting with pairs of high power pulses of, at that time, short duration—of the order of 1 ms. He found a signal at a time that no pulse was applied. After initially dismissing the 'weird signal' as an artifact, Hahn found that it was, in fact, reproducible. He had serendipitously discovered the spin echo! He understood

Figure 14 Vector representation of the formation of an 'effective field' from an off-resonance static magnetic field H_0 and an rf field H_1

Figure 15 Transient nutations at 9 MHz for glycerine at exact resonance (top), slightly off-resonance (middle), and farther off-resonance (bottom). Sweep time 0.01 s.⁴³ (Redrawn by permission of the American Physical Society)

that he was observing a free induction decay and eventually deduced from the Bloch equations what caused the 90° , 90° two-pulse echo. Understanding the three-pulse stimulated echo presented even more of a challenge. Hahn gives Purcell credit for first formulating a pictorial representation of a 90° , τ , 90° echo. (Only after several years did Carr and Purcell demonstrate the conceptually much simpler 90° , τ , 180° echo, as we shall discuss in Section 4.) During this period also, Hahn first observed a mysterious beat modulation in the echo envelope of the signal from ethyl alcohol but could not explain it at that time.

The use of short rf pulses and the observation of NMR by free induction decay (FID) signals would ultimately play a vital role in the development of sophisticated modern NMR methods, and we shall return in later Sections to more detailed discussions of advances in pulsed NMR methods. However,

about 1950 other discoveries began to change NMR from a technique for studying the properties of the nucleus to a method of examining the electronic environment around the nucleus—largely the province of chemists.

The Chemical Shift

All the early work in NMR was based on the assumption that the resonance frequency of a particular nucleus depends only on the applied magnetic field according to the Larmor relation. If this were strictly so, NMR would have remained an investigative method for physicists enlarging the table of precise nuclear magnetic moments and it would have been of little use in interdisciplinary sciences such as chemistry, biology, and medicine. However, it was fortunately observed as early as 1950 that NMR spectral frequencies of a particular species of nuclei in different chemical environments, whether in the same or different molecules, may be different and that the difference depends upon the molecular structure. This displacement is referred to as the *chemical shift*. As a matter of fact, the idea of the chemical shift is implicit in the earlier work of Knight (in 1949) discussed below.

The first observation of the chemical shift is a classical case of accidental discovery. In order to determine the magnetic moment of ^{14}N more precisely, Proctor and Yu⁴⁴ decided to use ammonium nitrate, NH_4NO_3 , which was available from the chemistry stockroom of the Stanford University. The main considerations for such a selection were the large solubility of the compound in water and the fact that it possesses two nitrogens per molecule, both factors expected to enhance the NMR signal. A saturated solution in water produced two strong lines instead of one! The observation was attributed to some 'nasty' chemical effect. About the same time, Dickinson⁴⁵ observed similar effects for ^{19}F in a variety of fluorine compounds such as $\text{C}_2\text{F}_3\text{Cl}_3$, SbF_3 , NaF , KF , HF , BF_3 , and BeF_2 . He employed two identical magnetic resonance absorption bridges, both fed by the same oscillator. The two sample holders were placed side by side in the magnet so that ^{19}F resonance occurred simultaneously on separate recording milliammeters. In these compounds the maximum separation of the ^{19}F resonances occurred for $\text{C}_2\text{F}_3\text{Cl}_3$ and BeF_2 , the former appearing at the lower applied field. The initial experiments were performed at a magnetic field of 0.7 T, and additional studies at 0.25 T demonstrated that the magnitude of the separations was proportional to the field strength.

At nearly the same time, Lindström⁴⁶ measured the nuclear magnetic moments of ^2H and ^1H in two different compounds (water and paraffin oil). He observed that the ratios of the magnetic moments for deuterons and protons in the two compounds were slightly different and so was the ratio of the magnetic moments for the protons in paraffin oil and water. Although the observations were published, no explanation of the effect was given. Thomas, on the other hand, in a later issue of the *Physical Review* in the same year⁴⁷ explicitly reported the measurement of proton chemical shifts between different compounds such as H_2 gas, water, and mineral oil.

The most dramatic demonstration of the chemical shift, and the real birth of 'high-resolution NMR' was the observation by Arnold, Dharmatti, and Packard⁴⁸ of separate lines for chemically nonequivalent protons in the same molecule,

Figure 16 An oscilloscope presentation of the three chemically shifted lines in ethyl alcohol.⁴⁸ (Reproduced by permission of the American Institute of Physics)

first acetic acid, then ethanol. Apparently it was Dharmatti, a chemist from India who was working in the physics department at Stanford, who suggested the molecules to be studied (see *Arnold, James T.: Early Perceptions in Nuclear Magnetic Resonance (NMR)* and *Packard, Martin E.: Nuclear Induction at Stanford and the Transition to Varian*). The separation of the chemically shifted lines was found to be field-dependent and only a few parts per million for protons. It was only with very small sample volumes and after substantial empirical searching in the magnet for a homogeneous spot that the separation of the spectral lines could be observed.

For ethyl alcohol, three spectral lines corresponding to the three different chemical groups, CH_3 , CH_2 , and OH , with relative intensities of 3 : 2 : 1, were observed as shown in Figure 16. This discovery really set the stage for the chemical applications of NMR, since it illustrated the ability of NMR to detect the presence or absence of particular groups of protons in a molecule, and the relative intensities provided a measure of the relative numbers of protons of each type.

This important discovery was possible only because of significant improvements in the instrumentation at Stanford, especially magnet homogeneity. The investigators used an electromagnet with 12-inch diameter pole faces, producing a field of 0.7 T in a 1.5-inch pole gap, designed by Harry E. Weaver, then also one of Bloch's students. This corresponds to the observation of the proton resonance at a frequency of approximately 30 MHz. To improve field homogeneity at the center of the magnet, shims were added to the magnet poles which were basically round with square edges. Enormous effort was required to locate the most homogeneous region in the magnetic field, hence a spherical sample only 1 mm in diameter was employed. Interestingly, however, Packard points out in his historical sketch that with great care further small splittings of the methyl and methylene lines could sometimes be observed, foreshadowing the later discovery of scalar spin-spin coupling. However, the published spectrum of ethanol was deliberately obtained under conditions where such barely resolved features were not evident.

Shortly after publication of the famous Arnold, Dharmatti, and Packard paper, Arnold observed that the separation between the OH and CH_2 peaks was temperature-dependent, whereas the CH_3 - CH_2 separation was not. Packard and Arnold reported this unexplained observation in an abstract

in the *Physical Review*,⁴⁹ and soon thereafter Liddel and Ramsey⁵⁰ explained the result as a consequence of hydrogen bonding between ethanol molecules. This observation of a resonance that shifts continuously with temperature (or, as was soon discovered, with dilution of the alcohol in an inert solvent such as CCl_4) implicitly demonstrated the consequence of rapid chemical exchange, a phenomenon that had not yet been explicitly elucidated and explained.

Perhaps the observation of the chemical shift should not have been so unexpected. In 1941, Lamb had developed a theory for magnetic shielding of single atoms,⁵¹ so qualitatively there was an explanation for the field-dependent variation in resonance frequency. However, the Lamb theory is inadequate to account for the magnitudes of the observed chemical shifts, and Ramsey showed in a series of papers in 1950–52 that other terms involving excited electronic states become important for nuclei other than hydrogen.^{52,53} The Ramsey theory provided a sound basis for interpreting chemical shifts and still provides the basic framework for all theoretical treatments of chemical shifts.

The discovery and explanation of the chemical shift had a profound influence on the direction that NMR was to take, since chemists began to take notice of its potential. Another related discovery of resonance frequency shifts in metals had a somewhat similar impact in solid state physics.

The Knight Shift

The search for new resonances was in full swing in the late 1940s, and Walter Knight who was doing research at Brookhaven National Laboratory was looking for antimony NMR. However, he observed instead a ^{63}Cu resonance without putting a sample in the probe! In checking the 'background' from the bare probe, Knight found a strong signal near the frequency expected for ^{63}Cu , which could arise from the probe coil, but its frequency was 20 kHz higher than expected from the standard table of nuclear magnetic moments. With a mixture of copper metal and copper(I) chloride, Knight found two well-resolved peaks (as shown in Figure 17), with the resonance of the pure metal appearing approximately 25 kHz above that for the nonmetallic salt, around the average frequency of 10 MHz. The measured relative shift was 0.23% (2300 ppm).

During the next few weeks several other metals such as sodium, aluminum, and liquid gallium were investigated. The effect was found to be common to all the metals. It was also observed that isotope pairs, such as ^{63}Cu and ^{65}Cu , possess equal shifts and the fractional frequency shifts are independent of the resonance field.⁵⁶ This fractional shift is at least an order of magnitude larger than the chemical shifts later found in different diamagnetic compounds. It was soon attributed to a hyperfine interaction between the magnetically polarized conduction electrons and the magnetic moments of the nuclei in the metal. This effect was later named the 'Knight Shift' by Bloembergen.⁵⁷ The Knight shift provides a sensitive means to probe structural effects and processes in metals, and Knight shifts have been used in many studies including melting of metals, metal-insulator transitions, normal-superconducting transitions, phase transitions, and magnetic couplings in metal alloy systems.

ZEEMAN, LARMOR, AND NMR

Many NMR books and articles refer to 'Zeeman splitting' of nuclear magnetic energy levels and to the 'Zeeman energy' of the nuclear spin system. In addition, NMR is often described in terms of 'Larmor precession' of nuclear magnetic moments and the nuclear resonance frequency is often called the 'Larmor frequency'. Neither Zeeman nor Larmor had anything to do with NMR; their relevant papers were published in 1897.

In a paper published in the *Philosophical Magazine*, P. Zeeman⁵⁴ reported 'On the Influence of Magnetism on the Nature of the Light emitted by a Substance'. He found that the well known yellow D lines emitted by sodium vapor when it is heated were broadened when the sodium chloride sample was placed in a magnetic field. Later work showed that the broadening was actually a splitting of the lines, and the term 'Zeeman effect' was applied to this phenomenon in optical spectroscopy. The term was generalized to include the splitting of energy levels through interaction with a magnetic field, regardless of the frequency and energy involved. Thus, the 'Zeeman interaction' of nuclear magnetic moments with an applied magnetic field is generally the dominant energy term in describing the nuclear spin system.

Sir Joseph Larmor followed up on Zeeman's observation and explanation of the optical spectroscopic phenomenon by publishing a theoretical analysis.⁵⁵ He treated the motion of charged particles moving in an elliptical orbit and calculated the change in their motion on the introduction of a uniform magnetic field. He showed that the original motion could be restored if the observer is located on a coordinate system rotating at a particular frequency dependent on the charge and mass of the particle. This formalism used to derive the 'Larmor frequency' was later found to describe the motion of other systems, such as magnetic moments interacting with a static magnetic field, and the terminology became standard in phenomenological treatments of NMR.

Indirect Spin-Spin Coupling

The discovery of this important concept is another landmark that led to the application of NMR to the investigation of molecular structure, conformation, and function. As many groups undertook independent investigations of NMR in the early 1950s, discoveries of new effects came so rapidly that it becomes difficult in many cases to identify unequivocally the real 'discoverer' of new phenomena. The discovery of indirect spin-spin couplings is one such example. In fact, independent work by several groups was essential before observations were even recognized as a new phenomenon and unraveled.

On careful examination of the NMR spectra under conditions of high resolution, it was observed that the chemically shifted peaks are themselves composed of several lines since the number of lines observed was more than required by simple consideration of nonequivalent nuclei. The multiplicity was first reported by Proctor and Yu⁵⁸ for the ^{121}Sb resonance in NaSbF_6 . In a carefully purified sample, ensuring that only one

Figure 17 Demonstration of the Knight shift in ^{63}Cu metal relative to the ^{63}Cu signal in CuCl powder.⁵⁶ (Reproduced by permission of the American Physical Society)

form of Sb was present, they observed five lines of different intensities, and Harry Weaver subsequently showed that there were in fact seven lines. They suggested a possible incomplete averaging of the magnetic dipole-dipole interactions between Sb and F by hindered rotation, but this explanation was shown not to account for the results.

Independently, Hoffman and Gutowsky while measuring the ^{19}F resonance in PF_3 observed two close lines of comparable intensity. The effect was also observed for PF_5 . It was difficult to explain this result until a systematic study of some fluorochlorophosphorus compounds was undertaken by McCall and Gutowsky.⁵⁹ The appearance of a 1 : 1 doublet in POCl_2F and a 1 : 2 : 1 triplet in CH_3OPF_2 for the phosphorus resonance ensured that the observation resulted from a new type of interaction, not (as had initially been thought) the presence of an impurity in the sample. It became clear that the splitting of the fluorine resonance depends upon the number of different phosphorus spin states, while the splitting of the phosphorus resonance depends upon the number of different fluorine spin states.

Meanwhile, Hahn and Maxwell observed the same effect in an entirely different manner, as 'slow beats' in the spin echo envelope for nonequivalent protons.⁶⁰ This turned out to be caused by the same interaction as the one in the steady-state multiplets.

Unlike chemical shifts, the magnitude of this splitting was found to be independent of the applied magnetic field,

and hence to represent an interaction not induced by the field. Unlike direct dipole–dipole coupling, the interaction did not average to zero with rapid molecular tumbling of the molecules in the liquid state. Thus this interaction was shown to be of the form of a scalar product, $J_{ij} \mathbf{I}_i \mathbf{I}_j$, where J_{ij} is a coupling constant related to the molecular structure. Ramsey and Purcell^{61,62} developed the theoretical explanation for the interaction as a slight polarization by the nuclear spins of the electron spins which are tightly coupled by exchange interactions in a chemical bond.

With the discovery and explanation of scalar coupling (or indirect spin–spin coupling) to complement the chemical shift, the groundwork had been laid for applications of NMR to chemistry.

NMR—A TOOL FOR CHEMICAL STUDIES

By 1952, when Bloch and Purcell received their Nobel Prizes, the basic principles of NMR had been established. Relaxation processes were generally understood and major parameters influencing the spectra, such as the chemical shift and scalar spin–spin coupling, had been elucidated. The potential of NMR for solving chemical problems had been demonstrated and the time was ripe for innovative chemists to mount a serious exploration of the uses of NMR in a wide range of problems in physical, organic, and inorganic chemistry—an exploration that would lead to an exponential expansion of its use. Although many important developments in the physical principles of NMR and its applications in solid state physics lay ahead, the next two decades were to be largely dominated by the chemical applications of NMR. As Martin Packard, one of the discoverers of NMR put it:

To borrow a phrase from a writer for Eastman Kodak: ‘Chemists got the point very quickly, thanked the physicists, and took over.’⁶³

An important factor responsible for the widespread and rapid advances of NMR in chemistry during the 1950s was the commercial availability of a high-resolution spectrometer and, moreover, the rapid progress in the improvement of NMR instrumentation.

The Varian NMR Spectrometer

Soon after the discovery of nuclear induction, Russell Varian sensed the commercial potential of the technique for chemical analysis—a remarkable leap of faith, since the only published spectrum at the time was that of water and the discovery of the chemical shift was still years away. He persuaded Bloch and Hansen to apply for a patent before the end of 1946 and to assign it to the not-yet incorporated Varian Associates. In fact, Russell Varian himself wrote most of the patent application. This patent, which was issued in 1951 but later modified, played a vital role in permitting Varian Associates to invest capital to produce commercial NMR instruments. Further interesting information on the patent is given in two historical sketches (*Anderson, Weston A.: Early NMR Experiences and Experiments* and *Packard, Martin E.: Nuclear Induction at Stanford and the Transition to Varian*

At first, Varian’s business lay principally in the sale of klystrons and later magnets for physics experiments. The first

real commercial NMR instrument was the free precession magnetometer, conceived by Russell Varian in 1948. The idea is simple: polarize the protons in a water sample in a magnetic field oriented perpendicular to the Earth’s magnetic field, then turn off the polarizing field and allow the nuclei to precess in the Earth’s field. The precession frequency then measures the magnitude of the field, and features such as geological formations or large steel objects (such as submarines), which perturb the field, can be identified. We shall describe some applications of this instrument in a later section.

The first commercial high-resolution NMR instrument, developed in 1952 and purchased by the Humble Oil Company, Baytown, TX, was primitive by today’s standards. It was designed for the study of protons at an operating frequency of 30 MHz and a magnetic field of about 0.7 T. The magnet was based on a design by Harry Weaver, then in Bloch’s laboratory at Stanford, and became the standard for Varian magnets for many years. It weighed 5400 lb, had 12-inch diameter pole faces separated by less than 2 inches, and required a large power supply containing eight 304-TL vacuum tubes, which produced significant heat. The magnet was water cooled. The pole pieces were made of high quality steel, and pole faces were polished to optical flatness to improve homogeneity. To adjust the pole pieces to be parallel to each other, small pieces of steel (‘shims’) were placed between them and the steel core of the magnet, and bolts tightened with a 12-ft long wrench. The magnet was specified to be able to resolve the three peaks of ethyl alcohol.

By 1953, the 30 MHz instrument was the state-of-the-art, top-of-the-line NMR spectrometer. It could resolve the fine structure from chemically nonequivalent protons in molecules as well as the hyperfine structure from spin–spin interaction between nonequivalent nuclei. The reproducibility of the spectral parameters was a problem which provided enormous scope for further developments. Sensitivity was such that only neat liquids or concentrated solutions would produce reasonable signal-to-noise ratios.

The operation of the system was not easy. The user had first to locate the signal from a sample of water and move the sample to the most homogeneous region, as judged by the persistence of ringing or ‘wiggles’ on the oscilloscope trace following a fast scan through resonance. Then the water sample had to be removed and replaced with the sample to be studied. Spectra were thus referenced to water only by noting the relative positions on the scope and hoping that the scan rate and magnetic field strength had remained constant while these measurements were being made. Many repetitions to check reproducibility were required.

Very important improvements in instrumentation were made over the next few years by Varian Associates’ staff, including Forrest Nelson, Ralph Kane, and a stream of physicists who came from Stanford—Warren Proctor, Harry Weaver, Weston Anderson, and James Arnold. James N. Shoolery joined Varian in 1952; more about that later. Many of the instrumental advances had their origin at Stanford. The commercialization of these discoveries is an early and markedly successful example of technology transfer from academia to industry, both through sharing of specific information and by Varian’s employing a number of highly trained and motivated people from Stanford.

Increasing the strength of the magnetic field while maintaining or improving its homogeneity has long been an objective

for high-resolution NMR, both because chemically shifted resonances can be resolved more easily and because sensitivity increases approximately at the $\frac{3}{2}$ -power of the magnetic field strength. By 1955, Varian had found that the 12-inch magnet and power supply could go to about 1.0 T, thus making 40 MHz operation possible for proton NMR. Three years later tapered pole caps and further 'beefing up' of the power supply raised the field to 1.4 T and the ^1H NMR frequency to 60 MHz.

Meanwhile, the magnetic field instability required that a spectrum be scanned by sweeping the field rapidly, thus limiting the precision of measurements and obscuring spectral details because of line distortions. A major improvement occurred when Varian introduced the 'super stabilizer', a device that sensed magnetic field variations as a current induced in a pickup coil placed near the magnetic field gap and generated a compensating current via a negative feedback loop. As described by Jim Shoolery (*Shoolery, James N.: High-Resolution NMR: A Dream Come True*):

Before magnetic flux stabilization was developed, obtaining a spectrum was like looking through binoculars at a row of birds on a telephone wire from the back of a truck bouncing over a rutted road. . . . I remember my first trial of the device in 1956. Closing the switch made it seem that I'd gotten out of the truck and mounted my binoculars on a tripod. I could easily count the birds on the wire and even tell if their feathers were ruffled. In a fit of enthusiasm, we called the device a Super Stabilizer.

As an interesting sidelight, just about this time Russell Varian patented a device that would ultimately displace the super stabilizer and become the standard method for controlling magnetic field strength—the field/frequency lock.⁶⁴ However, it would be five years before that principle came into use in the Varian A-60.

Probably no single advance contributed more to improvement of homogeneity than the use of sample spinning, about which an interesting story can be told.

Sample Spinning and Homogeneity Improvement

The limiting factor in high-resolution NMR measurements is often the inhomogeneity of the applied magnetic field and various measures have been taken to obtain the maximum homogeneity. The idea of sample spinning is one of them. Sample spinning in NMR first seems to have been employed in 1951 by Herman Y. Carr⁶⁵ in his Ph.D. work at Harvard University (*Carr, Herman Y.: Early Years of Free Precession Revisited*). In studies of spin echoes (about which we will say more in a later section), Carr realized that an echo could be produced by reversing the magnetic field gradient and that one way to do this is to rotate the sample by 180° . He spun samples attached to a motor by a long wooden shaft and, among other applications, observed the chemical shift modulation of the free induction decay in a magnet whose inhomogeneity otherwise obscured the chemical shift effects.

In 1954 Bloch, apparently unaware of Carr's unpublished work, suggested that if one could stir the sample rapidly within the sample tube, the effect of magnetic field variation over the sample could be drastically reduced. The idea for sample stirring occurred to Bloch one day at lunch as he was stirring his tea. He reasoned that stirring the nuclei would cause them to sense the average magnetic field.

Jim Arnold, then a graduate student, immediately fabricated a tiny glass paddle wheel that would fit into the 3-mm diameter

Figure 18 Excerpts from Felix Bloch's patent application for sample spinning.⁶⁸ The examples of nonspinning and spinning lineshapes came from the paper by Anderson and Arnold⁶⁷

sample tube and mounted it on the end of a long glass tube. When the paddle was spun by a tiny air turbine, he found a remarkable improvement in resolution. However, the paddle wheel, which created magnetic susceptibility discontinuities, soon gave way to the technically easier method of simply spinning the entire sample tube. Bloch's proposal for sample spinning⁶⁶ and an experimental demonstration by Anderson and Arnold⁶⁷ were published consecutively in the *Physical Review*, and Bloch patented the technique.⁶⁸ Spinning in excess of 10 rotations per second was shown to reduce the linewidth by a factor of 17, as illustrated in Figure 18. According to Kaplan's later work,⁶⁹ periodic rotation is generally more effective than random rotation in producing line narrowing. Williams and Gutowsky⁷⁰ and Halbach⁷¹ analyzed spinning in detail under conditions of magnetic field inhomogeneity.

The method achieves only partial homogeneity improvement since it effects an averaging over the field around coaxial circles in the plane normal to the spinning axis but does not average the field along the axis of spinning. Nevertheless, as sample spinning was introduced into the Varian 40 MHz instrument, 'high-resolution' NMR was finally achieved. Searching for optimum homogeneity was reduced largely to a one-dimensional problem, along the y axis, the axis of rotation of the sample in an electromagnet.

One innovation to improve homogeneity along the y axis had its origin also at Stanford. The requirement for an extremely high homogeneity magnet was often demonstrated to a visitor by having him push on the strong steel yoke of the 5400 lb magnet, whereupon the NMR signal displayed on an oscilloscope was observed to shift. The effect of such a tiny distortion was turned to advantage when Varian introduced the 'field trimmer', a device mounted on one side of the magnet that used a 1-ft long wrench to distort the magnet yoke and thus permit optimization of homogeneity along the y axis.

A final method of homogeneity improvement, developed initially in a crude form by Arnold and Anderson at Stanford, was the use of a number of electrical coils in which the current could be adjusted to generate small, accurately controlled magnetic field gradients that would compensate the unwanted

gradients in the main magnetic field. Since this method would perform the same function (albeit in a very different manner) as metal shims placed behind the pole pieces, the coils were initially called 'shim coils', a term that persists to the present. In 1955, Marcel Golay at the Perkin-Elmer Corporation designed sophisticated shim coils, initially for use by Rex Richards with his 7000 G permanent magnet, and various laboratories experimented with homemade shim coils. While simple in principle, the design of such coils was a challenge and they were not introduced commercially until about 1958.

Chemical Shifts, Chemical Exchange, and Chemical Structure

With the remarkable advances in NMR instrumentation and the availability of commercial NMR instruments, the door was opened for the participation of many more chemists in the NMR revolution. Meanwhile, pioneering chemists with homemade instruments continued to develop new concepts and to correlate NMR data with molecular structure. During the early to mid 1950s a solid foundation for the use of NMR in chemistry was erected.

As stated previously, in 1948 Herbert Gutowsky established an NMR program in the chemistry department at the University of Illinois that became a major center for new developments. Gutowsky and his co-workers initiated efforts to correlate chemical shifts with molecular structure.^{72,73} The ^{19}F nucleus was particularly attractive, since it has a spin of $\frac{1}{2}$, almost as high a sensitivity as ^1H , generally favorable relaxation times, and a large chemical shift range. In one of the earliest studies, they found that they could distinguish the ^{19}F resonances in a benzene derivative with a CF_3 group and three fluorines in the ring. Gutowsky and Hoffman studied a large number of fluorine compounds and in 1950 reported on the influence of molecular structure on fluorine chemical shifts.⁷² The initial observations suggested that in simple covalent compounds the magnetic shielding of an ^{19}F nucleus chemically bound to another element is related to the position of that element in the Periodic Table. For elements in the same period, the shielding was found to decrease with increasing atomic number, while for elements in the same group the shielding increases with increasing atomic number. In complex fluoro compounds, the shielding was found to depend upon the inductive effects of the neighboring chemical bonds. Saika and Slichter⁷⁴ developed a quantitative theory of the atomic contributions to the ^{19}F chemical shifts. The experimental observations of Gutowsky and Hoffman⁷⁵ reported in 1951 showed a fairly good correlation of the ^{19}F chemical shifts with the electronegativity of the atom to which the fluorine is bonded, a covalently bonded fluorine being less shielded than an ionic one. The ^{19}F and ^1H chemical shifts in halomethanes were employed by the same group to derive information on the ionic character of the C-H bonds and the double bond character of C-X bonds, where X is a halogen atom.

In 1953 Gutowsky's group also investigated the proton chemical shifts in a large number of organic compounds. Although proton chemical shifts were discovered only in 1951, Lee Meyer as early as 1952 started a survey of the shifts on a new homemade spectrometer at the University of Illinois.⁷⁶ The idea was to see the extent to which they are characteristic of the various functional groups such as CH_3 ,

Figure 19 Correlation chart for proton chemical shifts in various organic functional moieties, published by Meyer, Saika, and Gutowsky.⁷⁶ (Reproduced by permission of the American Chemical Society)

NH_2 , CH_2 , OH , etc. This work resulted in the correlation shown in Figure 19. This empirical relationship quickly became valuable for ascertaining the presence or absence of particular functional groups. The results were presented at a meeting of the American Chemical Society in Chicago in the fall of 1953. This correlation chart had an enormous impact on the chemistry community. It was used for a decade and served as the basis of every other proton chemical shift correlation developed with additional data in subsequent years, and was a model for other nuclei such as ^{13}C . It gave organic chemists the same type of feeling for the use of chemical shifts as a measure of molecular structure as the Colthup chart had provided for infrared spectroscopic data a decade earlier. Both types of correlations were undoubtedly oversimplified, but they provided an overall guide to the interpretation of the spectral data.

The ^{31}P nucleus was also studied extensively in early high-resolution NMR, since it has a chemical shift range of about 1000 ppm, possesses reasonable sensitivity, and gives sharp lines. An indication of the existence of phosphorus chemical shifts of about 0.01% among several phosphorus compounds was first given by Knight in 1949 in his seminal paper entitled 'Nuclear Magnetic Resonance Shift in Metals'.⁵⁶ Dickinson⁷⁷ in 1950, subsequently made a comparison of the differences in the magnetic shieldings for some phosphorus compounds and observed that large shifts occur between phosphorus-(III) and -(V). Soon after this, Gutowsky and McCall⁵⁹ made a detailed study of ^{31}P NMR in POCl_3 , POCl_2F , POClF_2 , and CH_3OPF_2 , and observed the chemical shifts and the indirect ^{31}P - ^{19}F spin-spin couplings wherever present. During the 1950s several hundred phosphorus compounds were subjected to NMR investigations. The ^{31}P chemical shift spread for trivalent phosphorus compounds was found to be much larger than that for pentavalent phosphorus. The effects of solvents, temperatures, substituents, molecular structure, and conformation on the chemical shifts and coupling constants were later studied in detail for a large number of systems, and useful empirical correlations between the NMR and structural parameters derived.

While experimental data were being acquired, many chemists were trying to understand chemical shifts (particularly ^1H chemical shifts) in terms of molecular structure. The early correlations by Gutowsky and others made it clear that electron-withdrawing substituents attached to a carbon atom resulted in deshielding of a bonded proton. Spiess and Schneider showed such correlations in detail, not only for ^1H but also for ^{13}C chemical shifts.⁷⁸ It soon became clear that magnetic anisotropy in neighboring functional groups also has a significant effect on chemical shifts. In particular, the presence of 'ring currents' of π -electrons in aromatic rings can cause significant shifts. Meyer, Saika, and Gutowsky⁷⁶ observed that the proton signals in benzenes were displaced to lower fields by about 1.4 ppm compared with those in ethylenes. Waugh and Fessenden⁷⁹ subsequently measured the shifts in dilute solutions in an inert solvent such as CCl_4 and made theoretical computations. The magnetic dipole model of Pople,⁸⁰ and a subsequent refinement by Johnson and Bovey,⁸¹ provided a means of making quantitative estimates of ring-current effects that have been used to the present day.

Another important development, initially largely at Illinois, was the recognition that the rate of chemical exchange could be estimated by its effect on an NMR spectrum. The role of fast exchange in averaging the chemical shifts of several coexisting species was recognized implicitly by Arnold and Packard⁸² in their classic study of hydrogen bonding in ethanol (which we shall discuss in Section 3.9). However, in the course of characterizing spin-spin couplings, Gutowsky and co-workers observed that fast exchange can average out splittings as well. They observed a fluorine doublet in aqueous solutions of HPF_6 but not in HF , while for the BF_4^- ion in aqueous HBF_4 no splittings were observed in the ^{19}F spectrum. The absence of splittings was attributed to the chemical exchange of fluorines among the BF_4^- ions. The theoretical treatment of the exchange effect was developed by Gutowsky, McCall, and Slichter⁸³ using Bloch equations. Subsequently, Gutowsky and Saika⁸⁴ examined the concentration dependence of the proton chemical shifts in aqueous strong acids. Because of fast exchange in these systems, the exchange rates could not be determined; only the concentration dependence of the shifts could be examined. However, the lineshapes in the regions intermediate between the fast and the slow exchanges for two equally populated sites were computed. The results indicated that chemical lifetimes in the range 10^{-2} to 10^{-4} s could be measured by such an approach. It was also proposed that the activation energy for the exchange could be evaluated from such studies. The classic example to demonstrate exchange effects was first provided by the study of N,N -dimethylformamide, where Phillips had found two lines for the nonequivalent methyl groups at room temperature.⁸⁵ Gutowsky and Holm⁸⁶ investigated the temperature dependence and found that the doublet observed at room temperature alters at higher temperature as internal rotation about the C-C bond leads to exchange. The exchange rate and the activation energies were computed. This opened the field for the study of a large number of exchange processes.

For example, at Caltech, John D. Roberts received one of the early Varian 40 MHz spectrometers and studied nitrogen inversion and various rotational isomerisms (*Roberts, John D.: A Personal NMR Odyssey*), along with many other structural organic problems. W. D. Phillips at DuPont, the purchaser of one of the earliest 30 MHz spectrometers (soon

upgraded to 40 MHz), had investigated hindered rotation in amides and other molecules before turning to studies of paramagnetic species and biopolymers (*Ferguson, Raymond C.: William D. Phillips and Nuclear Magnetic Resonance Spectroscopy at DuPont*). At the National Research Council of Canada, which was another early owner of a Varian 40 MHz instrument, William G. Schneider and Harold Bernstein studied a variety of organic and inorganic systems to derive physicochemical information and to develop further correlations of NMR parameters with molecular structure, largely in collaboration with John Pople (See *Schneider, William G.: Early Research on High-Resolution Proton Magnetic Resonance*). An increasing number of laboratories, both academic and industrial, too numerous to mention here, were drawn into the use of NMR at this still early phase of its use in chemistry.

Shoolery and the Applab

Shortly after receiving his Ph.D. at Caltech in 1952, James N. Shoolery became aware of the existence of Varian Associates and of its plans to offer a commercial NMR instrument designed for chemical studies. As he says in his historical sketch:

When I saw the three peaks of ethyl alcohol, I knew what I wanted to do and where I wanted to do it. I wrote to Varian, suggesting that a company far-sighted enough to offer such a technologically advanced product might consider employing a chemist to help develop applications for their instrument. I modestly announced that I would be available. To my delight, Varian Associates offered me the position.

Varian management realized that their task was not only to improve instruments but to develop the infrastructure that correlated NMR parameters with chemical structures. By the beginning of 1953 Shoolery had formally opened the Applications Laboratory ('Applab') at Varian Associates. He and his colleagues developed new experimental methods and new ways to interpret NMR spectra, and a number of chemists came to the Applab with problems that NMR might solve. By the middle of 1954, the chemical shifts and coupling constants had been measured for a wide range of compounds with known structures, but no really unknown structure had been elucidated solely by NMR. The first example showing that NMR could solve a significant chemical problem in a straightforward, direct, and simple manner occurred in a sample submitted by E. J. Corey.⁸⁷ As illustrated in Figure 20, the problem was to distinguish between the structures of cycloheptatriene (A) or bicycloheptadiene (B). The correct structure (a) was unambiguously established from the relative intensities of the olefinic and aliphatic protons.

Steps were taken to familiarize organic chemists with the potential of NMR for the elucidation of molecular structure. A publicity campaign was initiated by the widespread circulation of reports entitled *Technical Information from the Radio Frequency Spectroscopy Laboratories of Varian Associates*. These bulletins included information on instrumental developments and showed new spectra. Figure 21 shows a portion of the first *Technical Information Bulletin*, dated July 1953, which heralds 'A New Kind of Spectroscopy: High Resolution n-m-r'. The terminology represented a deliberate decision to de-emphasize the word 'nuclear' and emphasize the term 'spectroscopy' in

Figure 20 One of the earliest examples of the use of NMR in structure elucidation, as described in J. N. Shoolery's historical sketch, *Shoolery, James N.: High-Resolution NMR: A Dream Come True*. (Reproduced by permission of Varian Associates)

an effort to capitalize on the popularity of infrared (IR) spectroscopy. However, to carve out some independence from IR, peaks were shown pointed up rather than down as in IR in what was to become a universal format for high-resolution NMR spectra. Figure 22 illustrates some of the 'Typical Proton Signals' shown in this issue as photographs of oscilloscope traces.

By 1955, Volume 1, Number 3 of this bulletin featured an article 'Important New Spinning Sample Technique Improves n-m-r Resolution'. Also included were the first 12 spectra from 'This is NMR at Work', a series of advertisements published each month, first in *Analytical Chemistry*, then in the *Journal of the American Chemical Society*, demonstrating new applications of NMR. The state of the art at that time is illustrated in Figure 23, but the examples became far more sophisticated as the years went by. Chemists and the new breed of NMR spectroscopists awaited these advertisements as eagerly as they anticipated research articles. The rewards for such a methodology were great. Organic chemists soon found that NMR spectroscopy was an ideal technique for elucidating and verifying the structure of moderate-sized molecules. Almost every compound one could lay one's hands on produced new and interesting data.

A classic paper by Shoolery and Rogers⁸⁸ in 1958 demonstrated the usefulness of NMR spectroscopy in the study of relatively large molecules such as steroids. Even at 40 MHz, the proton NMR spectra of the 47 steroids studied exhibited informative features. As illustrated in Figure 24, the bulk of the steroid resonances appeared as a broad 'hump' of complex structure that the authors recognized was not interpretable but could serve as a general fingerprint sensitive to structural differences. Nevertheless, a large number of proton chemical shifts were correlated with structural features. These included resonances shifted to low field (from attachment to unsaturated or hydroxyl-substituted carbons), hydroxyl protons, and angular methyl groups. Axial protons in the 3-position were found to be shifted upfield by more than 0.5 ppm relative to equatorial protons. The chemical shifts of angular methyl groups were found to be particularly sensitive

to many aspects of structure, and these strong peaks could be observed readily even with small amounts of sample, as shown in Figure 24. This paper had a major impact in demonstrating the utility of NMR in important, practical applications.

In 1959, Goodwin, Shoolery, and Johnson published one of the first examples where the complete proof of the structure of an alkaloid was accomplished by NMR.⁸⁹ Illustrative of these early papers, the experimental section noted innovations such as flux stabilization and spinning of the sample tube during the recording of the spectrum. Audiofrequency side bands were used for frequency measurements and two recorders were run simultaneously at different gain settings in order to measure the line intensities of intense and weak signals. This work was begun in the Applab at the then standard proton frequency of 40 MHz, but while the study was in progress, prototype 60 MHz apparatus became available as project SMOFF, 'sixty megacycles or fifty-five', (see *Anderson, Weston A.: Early NMR Experiences and Experiments*) succeeded in upgrading the magnetic field. The resulting spectra of the alkaloids lunacrine and lunine, with frequencies measured to an accuracy of 0.1 Hz, could be completely interpreted, including an interesting observation of the nonequivalence of the two methyl groups in the isopropyl side chain.

Acquisition and Analysis of Complex Spectra

As chemists began to apply NMR to more complex molecules with instruments operating at 40 MHz or 60 MHz, spin systems were observed more frequently which gave spectra that were not amenable to first-order analysis. Methods had to be developed for analyzing such spectra, but also methods were needed for making accurate measurements of line positions. By the latter part of the 1950s, it was possible to obtain (with considerable effort) adequate homogeneity to produce lines of 0.5 Hz width and, in principle, measurements of line positions could be made to a fraction of this value. However, before the field/frequency lock was implemented, each spectrum had to be calibrated individually, and for precise measurements the experimenter could not rely on a field-sweep scan to be linear over any appreciable range. Two experimental methods were widely used to measure line frequencies. Audiofrequency modulation of the magnetic field (or occasionally of the fixed radiofrequency) generated amplitude modulated sidebands spaced at the audiofrequency, which could be measured independently by a frequency counter to at least 0.1 Hz. Hence, an arbitrarily small portion of a spectrum could be calibrated or a sideband of a reference frequency could be superimposed precisely on a given spectral line to determine its separation from the reference. By using a moderate scan rate that produced ringing or 'wiggles' after the line, exact coincidence of the spectral feature and the audio sideband could be observed on an oscilloscope and the frequency measured quite precisely, often to about 0.1 Hz (about 0.002 ppm at 60 MHz). A second method which made use of the ringing is the *wiggle beat method* for measuring the frequency separation of two closely spaced lines.⁹⁰ Again, a moderate rate scan produced wiggles after each line, which then interfered with each other to produce a beat pattern. From the frequency maxima of the beats, the line separations could usually be obtained to about 0.02 Hz,⁹¹ depending on magnetic field homogeneity and T_2 , which determine duration of the

A NEW KIND OF SPECTROSCOPY: HIGH RESOLUTION n-m-r

INTRODUCTION

n-m-r (Nuclear Magnetic Resonance) Spectroscopy is based on the fact that the various isotopes of the elements can be separately identified according to their differing nuclear *gyro-magnetic* constants. Just as there is a certain mass and electric charge associated with each isotope, so there is a spin, or angular momentum, associated with each isotope. It has been found that all those isotopes whose spins do not have the value zero also possess a magnetic moment — that is, each behaves as though it were a tiny magnet with a well-defined, unique magnetic strength. The ratio of the magnetic moment value to

the spin value, which is a constant for a given atomic nucleus, is called the *gyro-magnetic ratio* for that particular nucleus. The fact that these ratios differ from isotope to isotope permits separation and identification according to the scheme of n-m-r Spectroscopy.

It will become evident further on that a special version of this new kind of Spectroscopy—High Resolution—represents a penetrating new method for, among other things, determining molecular structure and identifying and measuring components in a mixture.

Figure 21 Portion of the first issue of the Varian *Technical Information Bulletin*. (Reproduced by permission of Varian Associates)

beat pattern. Measurements were, of course, repeated several times for maximum accuracy and field sweeps obtained in both directions. Viewed in the context of modern Fourier transform instruments with very precise frequency and phase control, it is remarkable how well the measurements made by investigators with the relatively crude instruments of the 1950s agree with current data.

When scalar coupling was first discovered, general rules governing the multiplicity of the NMR spectral lines were developed on the basis of statistical considerations: (i) If a nucleus of spin $\frac{1}{2}$ has n equivalently coupled neighbors of spin $\frac{1}{2}$ each, its resonance splits into $n + 1$ peaks corresponding to $n + 1$ spin states of the neighboring groups of spins. (ii) The peak intensities are determined by simple statistical

considerations and are proportional to the coefficients of the binomial expansion. These 'rules' worked very well when applied to the initial systems studied which largely involved nuclei of different species coupled to each other, hence with scalar couplings that are much smaller than the frequency differences caused by chemical shifts. Such spectra are referred to as 'weakly' coupled as compared with those called 'strongly' coupled, where the indirect spin-spin couplings and the chemical shifts are of comparable magnitudes. Even in the early 1950s the distinction was clear to physicists well versed in quantum mechanical principles; for example, at Stanford, Arnold analyzed the splittings in ethanol by means of a second-order perturbation treatment, as illustrated in his historical sketch (*Arnold, James T.: Early Perceptions in Nuclear Magnetic Resonance (NMR)*). However, it was not

widely appreciated by the early chemists using NMR that, in strongly coupled cases, the derivation of the chemical shifts and coupling constants does not follow the simple rules but must be treated by more rigorous quantum mechanical methods.

The paper by McConnell, McLean, and Reilly⁹² in 1955 pointed the way to general methods for dealing with such systems. Soon Pople, Schneider, and Bernstein undertook careful analyses of a variety of spin systems and introduced the now universally used system of classifying spin systems by using letters close to each other in the alphabet (e.g., A, B) to denote strongly coupled systems and those far from each other (e.g., A, M, X) for weakly coupled nuclei. Several papers demonstrated the application of well-known symmetry considerations to NMR spectra, and the concept of 'magnetic equivalence' became more widely appreciated. With this framework, a number of investigators analyzed spin systems that possessed elements of symmetry and/or large chemical shift differences. Under these circumstances the Hamiltonian matrix could be shown to reduce to blocks no larger than 2×2 , which were readily subject to algebraic solution. The book by Pople, Schneider, and Bernstein⁹³ in 1959 provided a comprehensive treatment, but application to specific spin systems was not always straightforward in 1960, as described by Aksel Bothner-By in his historical sketch (*Bothner-By, Aksel A.: Computer Analysis of High-Resolution NMR Spectra*):

Even with the algebraic solutions in hand, the task of tabulating all the line frequencies and intensities and finding the values of shifts and coupling constants giving a spectrum agreeing with the observed one was tedious, error-prone, and time-consuming. The availability of an IBM 650 through the newly formed Department of Computer Science at the Carnegie Institute of Technology appeared to offer a fast and convenient way to tabulate these spectra, and we set out to write a few programs for specific cases, such as $X_3AA'X'_3$, applicable to the case of the 2,3-dihalobutanes, which we were then studying. From Alan Perlis, the Director, we received a set of instructions in how to prepare a program for the computer in a language called IT. After a couple weeks of puzzling, we produced what we thought would be a working program and brought it to be run. Unfortunately, IT had become obsolete in the interim, and a new language, AT, was now in use. Our second attempt also took about two weeks to write, and, predictably, was also out-of-date when we got it there. Back, to rewrite in GAT. This time we were barely in time, and, amazingly to us, it worked. The computer gave us a list in about two minutes that it would have taken us two days to crank out on a Monroe. We were able to use it for the intended analyses.

Many spin systems, however, could not be treated in this way. Even such simple systems as ABC require the solution of cubic equations and cannot be treated, in general, by algebraic procedures. On the other hand, if estimated numerical values for chemical shifts and coupling constants are introduced, the diagonalization problem becomes purely numerical. Numerical methods for the interactive diagonalization of large symmetric real matrices had long been known and can be conveniently employed with the help of an appropriate computer, but in the late 1950s such computers were in their infancy. Computer programs to read in a set of assumed chemical shift and coupling constant values, evaluate the numerical Hamiltonian, perform the diagonalization, and provide calculated frequencies and intensities for the expected spectra were first

developed in 1960. Aksel Bothner-By's FREQINT was one of the first and most popular of these first generation programs.

GORDON RESEARCH CONFERENCES ON MAGNETIC RESONANCE

By the mid-1950s, magnetic resonance (including both nuclear and electron spin resonance) had become sufficiently well established as to warrant the establishment of a Gordon Research Conference in this field. Gordon Conferences had achieved a reputation in a wide variety of topics as a forum in which about 100 active participants in a field could spend a week exploring the frontiers in that area.

The first Gordon Conference on Magnetic Resonance was held in 1958 under the chairmanship of Herbert Gutowsky. Attendees formed a veritable 'who's who' in the rapidly expanding field. Among well-known NMR figures who presented talks or chaired sessions were Harden McConnell, Jim Shoolery, Harold Bernstein, John Zimmerman, John Pople, Saul Meiboom, Nicolaas Bloembergen, Charles Reilly, Dave McCall, Ben Dailey, Martin Karplus, John Waugh, George Pake, Bob Shulman, Ned Baker, and Wes Anderson. Many other then and future eminent figures in the NMR and ESR fields also participated actively. Titles of talks were usually quite broad, e.g., 'Interpretation of High-Resolution NMR Spectra and Current Chemical Applications'; 'Methods of High-Resolution Spectral Analysis'; 'NMR in Magnetic Solids'; and 'Theoretical Interpretation of Electron-Coupled Spin-Spin Interactions'.

The first meeting was so successful that the participants recommended a second meeting in 1959, before going to the biennial schedule that the Conference has followed in subsequent years.

In 1974, in recognition of burgeoning new aspects of NMR applications, a Gordon Research Conference on Magnetic Resonance in Biology and Medicine was established and continues to meet biennially.

One difficulty with the initial programs was that the spectra were computed from the assumed chemical shifts and coupling constants, whereas what was needed was the reverse process, namely the computation of chemical shifts and coupling constants from the spectrum. For quantum mechanical problems of this sort, 'direct' methods of inputting frequencies and deriving the desired parameters are mathematically cumbersome, and have been developed only for the simplest systems (ABC). Consequently, iterative programs providing the 'best' fit values of chemical shifts and coupling constants were subsequently developed. In such programs, either energy levels or spectra are first computed from trial values of the parameters, and the observed and computed spectra are compared. The parameters are then automatically changed such that the sums of the squares of the deviations between the observed and the computed line positions are minimized. Various versions of the programs which have been commonly used were developed by Reilly and Swalen,⁹⁴ Hoffman,⁹⁵ and Bothner-By et al.⁹⁶⁻⁹⁸ (see *Bothner-By, Aksel A.: Computer Analysis of High-Resolution NMR Spectra*). All these programs use the frequencies of the spectral lines for the computations and do not take into account the intensities of the lines. The intensities were subsequently used qualitatively for confirming the

Figure 25 Analysis of an AA'BB' spectrum.¹⁰⁰ (Reproduced by permission of the American Institute of Physics)

parameters deduced from the iteration, an appropriate procedure in view of the fact that the precision with which the frequencies could be measured was far better than that for the intensities. In 1962, Arata, Shimizu, and Fujiwara⁹⁹ proposed a method in which the intensities were also included in the iterative procedures, but this procedure has not been used in any significant investigations. Figure 25 illustrates the result of a typical analysis, this one carried out by a related iterative method developed by Martin and Dailey.¹⁰⁰

The most widely used program is the one developed by Castellano and Bothner-By, LAOCOON II and its subsequent versions LAOCOON III and LAOCN. These programs were soon modified to improve the efficiency and expand the usage. In 1965, Haigh¹⁰¹ added the capability of handling groups of magnetically equivalent spins in order to improve the efficiency. Diehl, Khetrpal, and Kellerhals¹⁰² adapted the software to include direct dipolar couplings in the Hamiltonian so that the spectra of molecules oriented in liquid crystals could be analyzed, and named the program as LAOCOONOR. Several other groups have included nuclei with spin $> \frac{1}{2}$ and treated quadrupole couplings. Later analyses focused on the fact that multiple minima are possible in the multiparameter space, hence that different sets of parameters might provide equally acceptable fits of observed spectra.¹⁰³ Modern versions of these programs are now commonly available as part of the standard NMR spectrometer software.

Meanwhile, attempts were also made to find simpler analysis procedures as far as possible without the use of a computer, at least in certain special cases. In this connection, Pople and Schaefer¹⁰⁴ and Diehl and Pople¹⁰⁵ in 1960 carefully examined the theoretical expressions for the frequencies and the intensities of spectral lines in cases where two nuclei have a relative chemical shift comparable with their spin-spin coupling constant and all other relative chemical shifts are large, i.e., systems of the type ABR_pX_q and AB_2X_q . They observed that all such systems could be handled within one

theoretical scheme and the multiline spectra could be built up as the superposition of the spectra of simpler types and treated by *sub-spectral analysis*.

During the early 1960s the sub-spectral approach became quite popular when computer programs were not yet fully developed and helped to explain the concept of 'virtual coupling'. This procedure has also been utilized for the analysis of complex spectra of certain molecules oriented in nematic liquid crystals. For example, monodeuterobenzene (an AA'BB'CP system, where P is the spin-1 deuterium) was treated as the superposition of three five-spin sub-spectra.¹⁰⁶

Influence of Molecular Conformation on NMR Spectra

In 1957, Reid¹⁰⁷ demonstrated that chemically similar protons in fused aromatic rings were chemically shifted when their immediate environments were different, and it was found that in saturated six-membered rings equatorial protons normally resonate downfield compared with the chemically equivalent protons in the axial orientation in some substituted cyclohexanes and in symmetrical trioxanes.

The correlation of indirect spin-spin coupling constants with molecular structure was another area in which efforts were concentrated around the same time. By the late 1950s, sufficient data on proton-proton couplings had become available to establish several correlations with molecular structure. For example, it was found that in ethylene derivatives $J_{gem}(H,H)$ was very small, while $J_{trans}(H,H) > J_{cis}(H,H)$. Likewise, in acetylated aldopyranose sugars, Lemieux et al.^{108,109,110} showed that the three-bond axial/axial couplings between the protons on neighboring carbon atoms are two to three times as large as those involving equatorial protons. These observations had a very significant impact on the development of carbohydrate chemistry, as described in more detail in Lemieux's historical sketch.

Meanwhile, Martin Karplus developed a theory based on a valence-bond approach for the variation of the three-bond vicinal coupling constant with dihedral angle.¹¹¹ This theory was extremely successful in interpreting the salient features of the experimental HH, HF, and FF couplings in aliphatic and ethylenic compounds. The experimental observation that the *trans* coupling is always larger than the *cis* could be explained quantitatively. Karplus concluded that the vicinal coupling (J) for protons on adjacent saturated carbons should depend upon the dihedral angle ϕ according to the relation:

$$\left. \begin{aligned} J &= 8.5 \cos^2 \phi - 0.28 \text{ Hz} & (\text{for } 0^\circ < \phi < 90^\circ) \\ J &= 9.5 \cos^2 \phi - 0.28 \text{ Hz} & (\text{for } 90^\circ < \phi < 180^\circ) \end{aligned} \right\} \quad (3)$$

Unfortunately, as pointed out by Karplus in his historical sketch (*Karplus, Martin: Theory of Vicinal Coupling Constants*), many chemists believed that the relationship was more accurate than the approximations in the theory would allow:

Most people who use the 'Karplus equation' appear not to have read the original paper and so did not know the limitations of the theory cited there. They assumed that because the equation had been used to estimate vicinal dihedral angles, the theory said that the coupling constant depend *only* on the dihedral angle. By 1963, I had learned that important organic chemists write and read only communications to the *Journal of the*

American Chemical Society and so I decided to publish such a Communication,¹¹² in which I described various factors, other than the dihedral angle, that are expected to affect the value of the vicinal coupling constant; they include the electronegativity of substituents, the valence angles of the protons (HCC' and CC'H'), and bond lengths. The main point of the paper was not to provide a more accurate equation, but rather to make clear that caution had to be used in applying the equation to structural problems. My closing sentence, which has often been quoted, was the following: 'Certainly with our present knowledge, the person who attempts to estimate dihedral angles to an accuracy of one or two degrees does so at his own peril'.

Even with these limitations, the Karplus equation has become the cornerstone in the application of NMR to conformational analysis. This relation has proved to be durable over more than 30 years, with subsequent empirical modifications of the parameters to reflect their variation as a function of other aspects of molecular environment. The development of carbohydrate chemistry owes much to this relation and, as we shall see, three-dimensional structure determinations of proteins by NMR make extensive use of the Karplus relation. A previous theoretical treatment of geminal H–H coupling constants in saturated hydrocarbons by Karplus et al.¹¹³ did not fare as well. Initially this calculation appeared to reproduce very well a number of measured coupling constants on the assumption that these values of 2J are all positive. However, Cynthia Juan (later Jameson), a graduate student in Gutowsky's laboratory, found that the AA'BB' spectrum from the $-\text{CH}_2\text{CH}_2-$ fragment in metacyclophane could be fitted only by assuming opposite signs for the vicinal and geminal coupling constants. As Jameson describes in her article (*Jameson, Cynthia J.: Early Work on the Ranges of Chemical Shifts and Signs of Coupling Constants*), it was only after considerable effort to disprove this result that the finding was published.¹¹⁴

Meanwhile, Lemieux and co-workers had made a similar discovery. During the course of their work on monosubstituted 1,3-dioxolanes, they concluded that the geminal and the vicinal proton–proton couplings were of opposite signs. They submitted this work for publication to the *Journal of Chemical Physics*, but the paper was rejected, presumably because the conclusions were contrary to the published theoretical expectations—an indication of how difficult it is to 'sell' a new product! The paper was finally published in the *Journal of the American Chemical Society*,¹¹⁵ and Karplus later determined that the erroneous conclusion in the initial theoretical paper resulted from the fact that the calculation relied on a small difference between two large quantities.¹¹⁶

¹³C Satellites

While assessing the sensitivity of their NMR spectrometer in 1958, Cohen, Sheppard, and Turner¹¹⁷ made a very important discovery when they noticed in the proton NMR spectrum of CHCl_3 under high amplification two weak signals placed symmetrically (isotope effects were too small to be observed) about the main central line, with a total intensity of ca. 1% of the intensity of the main central band. They could not be attributed to spinning sidebands since they did not shift with a variation of the spinning frequency, and were eventually explained as 'satellites' arising from the 1.1% of the molecules

containing ¹³C with a frequency separation equal to $J(^{13}\text{C},\text{H})$. The ¹³C satellites of dioxane showed that J couplings could be extracted even though the main proton spectrum was a singlet. The method proved to be of great importance in permitting the measurement of vicinal coupling constants in symmetric molecules, which was especially important in testing theoretical predictions. Later, satellites due to other nuclei (e.g., ²⁹Si and ¹⁹⁹Hg) would be exploited in such studies and in double resonance measurements of chemical shifts.

Direct Observation of Carbon-13 NMR

As the key structural element in organic chemistry, carbon was an early target for NMR investigation, but the combination of only a 1.1% natural abundance for ¹³C, the only isotope with a nuclear spin, and its relatively low sensitivity made studies difficult with the limitations of instruments in the 1950s. Despite the adverse factors, the first ¹³C NMR spectrum was reported by two independent workers, Paul Lauterbur¹¹⁸ and C. H. Holm,¹¹⁹ who published their results in the same issue of the *Journal of Chemical Physics* in 1957. Most of the compounds that were studied were pure liquids and a signal-to-noise ratio of up to 50 could be achieved. Lauterbur alone studied over 100 compounds, while Holm presented the chemical shift data in the form of a chart (Figure 26) which emphasized the role of substituents. The range of ¹³C chemical shifts in neutral organic compounds was found to be about 20-times greater than that for protons. Only one-bond couplings of ¹³C with protons and ¹⁹F could be resolved. The directly bonded ¹³C–H coupling constants were found to vary between about 120 Hz and 210 Hz, depending on the bond hybridization and substituents present. The ¹³C–¹⁹F couplings in some fluorobenzenes were measured as 600 ± 20 Hz.

Despite the poor resolution and sensitivity, a few other intrepid workers, including J. B. Stothers, and Spiess and Schneider, joined the efforts to explore ¹³C chemical shifts and one-bond couplings in a large number of compounds and to develop correlations of the data with molecular structure, substituent properties, solvent, and temperature. For example, a linear relationship was observed by Lauterbur¹²⁰ between ¹³C chemical shifts in methyl halides and the electronegativity of the halide, and similar correlations were found by Spiess and Schneider.⁷⁸ Stothers, in particular, accumulated a vast amount of information on ¹³C NMR parameters and eventually published the first book with large compendia of ¹³C spectral data.¹²¹ In 1961, Gary Maciel began studies of ¹³C, as he relates in his historical sketch (*Maciel, Gary E.: A Little Polarization Can be Good for You*).

Lauterbur's initial observations of ¹³C spectra, along with most other early studies, were carried out with 15-mm diameter sample tubes without spinning, which severely limited resolution. In addition, the early work employed rapid passage dispersion mode operation rather than normal absorption mode in order to use high radiofrequency power to detect the weak signal without saturating it. Although this technique resulted in an improvement in the signal-to-noise ratios, the lines were further broadened. In 1962, Shoolery¹²² made a significant advance when he employed normal slow sweep absorption mode operation with spinning of a large sample tube to obtain good resolution without sacrificing sensitivity. This improvement was made possible by the

Figure 26 ^{13}C chemical shifts as tabulated by Holm.¹¹⁹ (Reproduced by permission of the American Institute of Physics)

application of phase-sensitive detection and audio modulation to improve baseline stability. He was able to resolve the two-bond ^{13}C -H coupling in acetic acid, as shown in Figure 27, the first observation of such couplings in ^{13}C spectra.

A new era of high-resolution ^{13}C NMR had begun, but further advances would depend also on the use of double resonance, as we shall discuss in Section 6.

Molecular Interactions and Hydrogen Bonding

In 1951, soon after the discovery of the proton chemical shift in ethanol, Packard and Arnold⁸² made another landmark discovery by observing that the chemical shift of the OH proton in ethanol exhibited strong temperature dependence, whereas the shifts of the CH_2 and CH_3 protons did not vary with temperature. A few months after this finding was published, Liddel and Ramsey⁵⁰ explained the results as probably arising from the effects of hydrogen bonding. They also proposed a test for this interpretation by pointing out that similar results should be observed by diluting ethanol with a nonhydrogen-bonding solvent such as CCl_4 . Arnold and Packard did just that and reported their experimental confirmation of the interpretation on the same page with the Liddel-Ramsey paper.¹²³

The high-frequency shift on hydrogen bonding became an important factor in interpreting ^1H NMR spectra since the proton chemical shifts of OH, NH, and SH protons were all found to be temperature (and solvent) dependent. In addition, the chemical shift of the hydrogen-bonded proton became

Figure 27 Comparison of the ^{13}C spectra of acetic acid obtained by rapid passage without spinning¹²⁰ (top) and slow sweep with spinning¹²² (bottom). (Upper portion reproduced by permission of the New York Academy of Sciences)

valuable for diagnostic purposes in structural elucidations when intramolecular hydrogen bonds were present. Among early work on the study of the hydrogen bonding by NMR was the observation of the shift in the ammonia-water system by Ogg¹²⁴ in 1954.

As higher resolution instruments permitted more precise measurements of chemical shifts, the hydrogen-bond effect was exploited by a number of workers to make quantitative measurements of hydrogen-bonding equilibria. For example, in 1955, Huggins, Pimentel, and Shoolery investigated the chloroform-acetone and chloroform-triethylamine systems¹²⁵ and the complex equilibria in phenol in CCl_4 ,¹²⁶ while Cohen and Reid,¹²⁷ Becker, Liddel, and Shoolery,¹²⁸ and Saunders and Hyne¹²⁹ reported similar observations on alcohols. The question of the possible correlation of the hydrogen-bond shifts with the strength of the hydrogen bonds was examined by Korinek and Schneider¹³⁰ in 1957, and the trend was found to be encouraging.

These observations subsequently provided a valuable new technique not only for the study of well known hydrogen bonds but also for the investigation of other even weaker molecular interactions. For example, the shifts in ethylene and acetylene were interpreted by Schneider, Bernstein, and Pople¹³¹ in terms of 'self-association' in which the hydrogen atoms of one molecule interact with the π -electrons of a neighboring molecule. Reeves and Schneider observed particularly large upfield shifts for CHCl_3 bonded to the face of an aromatic ring.¹³² Dilution of benzene or other aromatics in nonaromatic solvents was shown to lead to significant shifts which could be understood in terms of the diamagnetic anisotropy of benzene and the ring current

from its π -electrons. In 1960, Buckingham, Schaefer, and Schneider provided an enduring framework for explaining solvent effects in terms of van der Waals interactions, electric field effects, anisotropic interactions, and specific interactions such as hydrogen bonding.¹³³

FURTHER DEVELOPMENTS IN THE PHYSICS OF NMR

If the chemists 'took over' NMR in the late 1950s, the physicists were not really aware of it. Although the availability of commercial instruments opened up NMR research and applications to chemical problems, a great deal of important basic physics in NMR was yet to be discovered and developed (by both physicists and physical chemists), and applications to significant problems in solid state physics were just beginning.

Pulse and Spin Echo Methods Mature

Hahn had demonstrated what Bloch predicted, excitation by an rf pulse and acquisition of data in a free induction decay (FID). Hahn's spin echo had introduced a fundamental principle to NMR: reversibility. He showed that some processes that appeared on the surface to be irreversible could, in fact, be reversed. The spin echo from a $90^\circ, \tau, 90^\circ$ pulse sequence also gave promise of measuring the real T_2 value for a nuclear spin in a magnetic field that is so inhomogeneous that the decay of the FID is dominated by inhomogeneity. But, in practice, this simple spin echo experiment did not lead to reliable values of T_2 , largely because of molecular diffusion.

Carr and Purcell made several significant improvements over Hahn's methods.¹³⁴ First, they showed that a $90^\circ, \tau, 180^\circ$ pulse sequence is much simpler to understand. Their illustration of the formation of a spin echo (Figure 28) became the basis for countless diagrams in future papers and books. Second, they showed how a $180^\circ, \tau, 90^\circ$ pulse sequence could be used to measure T_1 . Third, they showed a way to overcome the effects of diffusion in a spin echo experiment by using a series of 180° pulses whose spacing could be made short enough so that any diffusion effects are negligible. The Carr–Purcell method also showed that diffusion effects could, in fact, be measured by a variation of the pulse spacing.

The Carr–Purcell spin echo method, although elegant, nevertheless fell short in making reliable measurements of T_2 because inhomogeneities in the rf field B_1 caused cumulative errors as the number of 180° pulses increased. At the instigation of Felix Bloch, the Weizmann Institute of Science in Israel set up an NMR laboratory in 1954 under Saul Meiboom. This group would go on to develop a number of innovations in NMR technology, as described by Zeev Luz in his historical sketch (*Luz, Zeev: The Early Days of NMR in Israel*). In applying the Carr–Purcell method, Meiboom and Gill¹³⁵ found that by simply changing the phase of the 180° pulses relative to the initial 90° pulse it was possible to compensate for the B_1 inhomogeneity effects. This paper is recognized as the first to emphasize phase relationships among pulses, a factor that would be critical to later developments. Widespread use of this method was delayed for years because the pulse spectrometers of that

era rarely incorporated phase-shifting devices or used phase-sensitive detection. Eventually, however, the combination Carr–Purcell–Meiboom–Gill (CPMG) method became the standard, not only for measuring T_2 but also for carrying out many more sophisticated pulse experiments.

Carr's Ph.D. work at Harvard with Purcell is remarkable for the number of innovative experiments that were conducted (*Carr, Herman Y.: Early Years of Free Precession Revisited*). Reference has already been made in Section 3.2 to Carr's work on sample spinning as a means of reversing the effect of magnetic field gradients. Many years later the method of gradient reversal was to assume a major role in NMR imaging, as we shall see later. Likewise, his analysis of the effects of coherent motion on the phase of the NMR signal has had an impact on flow measurement, as in magnetic resonance angiography. Two more aspects of his work are particularly noteworthy.

Long before Fourier transform NMR methods had revolutionized the field (as we shall see in subsequent sections), physicists were aware of the Fourier transform relation between a FID and a slow passage NMR spectrum. Lowe and Norberg, in their study of the NMR spectra of solids (*Lowe, Irving J.: My Life in the Rotating Frame*) derived the relation formally.¹³⁶ Much earlier, however, Carr and others had made 'mental' Fourier transforms of FIDs. For two or three lines of equal intensity, it was not too difficult to make the mental transform and picture the CW spectrum. However, for systems with unequal line separations and unequal intensities (e.g., $\text{CH}_3\text{CH}_2\text{OH}$) the process was more difficult, and to convince others Carr made what in current NMR imaging would be called a 'phantom', three pieces of rubber of volumes 3 : 2 : 1 which were placed in a magnetic field gradient that simulated the chemical shifts in ethanol. The FID obtained from this phantom agreed with that from liquid ethanol itself, thus verifying Carr's interpretation but also providing what may be (inadvertently) the first one-dimensional NMR image ever recorded. It would be 20 years before the idea of deliberately applying a field gradient to obtain spatial images would surface (see Section 13), and with only limited computers and programs available the possibility of using Fourier transforms to improve the acquisition of NMR spectra was given little or no thought.

With the CPMG method it was possible to measure translational diffusion in liquids. Donald Woessner (*Woessner, Donald E.: In a Maze in NMR*) realized that if molecular diffusion is restricted by the presence of small pores in a solid material, the diffusion coefficient D could be measured correctly with small interpulse spacing τ , but at long τ the molecules could not continue random diffusion because of collisions with the solid matrix and the apparent value of D would become smaller. Woessner tested the idea and verified the concept,¹³⁷ but it lay to Stejskal and Tanner (*Stejskal, Edward O.: Reminiscences about the Development of Pulsed Field Gradient, Spin-Echo NMR (PFGSE NMR)*) to overcome the technical obstacles in making diffusion measurements by introducing short pulsed gradients separated by a well-defined diffusion time.¹³⁸ This method permits easier and more precise measurement of the spin echoes in a homogeneous field. Although the PFGSE technique worked very well, it was difficult to implement with the NMR instruments of the 1960s. Currently, as we shall see later,

Figure 28 Schematic diagram of the behavior of precessing spins with a $90^\circ, \tau, 180^\circ$ pulse sequence to form a spin echo

the PFGSE method is a standard aspect of functional NMR imaging measurements.

Another important advance in spin echoes was the observation in 1954 of an echo in pure nuclear quadrupole resonance (NQR) which involves nuclear magnetic transitions among quadrupole split energy levels in zero magnetic field. Myer Bloom found the echo while he was a graduate student with Charles Slichter at the University of Illinois. According to Slichter (*Slichter, Charles P.: Early Days of Magnetic Resonance Studies of Solids*):

Myer Bloom ... came to me to propose that it should be possible to produce spin echoes in pure quadrupole resonance. He proceeded to do a long calculation ... to verify the theory. Meanwhile, I developed a simple symmetry argument which convinced me echoes would not form. ... I suggested that he find my error. ... Instead of tracking down my error, Myer and Dick [Norberg] (without telling me) set out to observe quadrupole echoes of Cl nuclei. One morning when I arrived at work, I found a scope photo of Myer's quadrupole echo on my desk!

Meanwhile, at Queen Mary College in London, Peter Mansfield, a graduate student with Jack Powles, was studying relaxation in polymers. During the course of this work, he applied two 90° pulses within about $3\text{--}4\ \mu\text{s}$ and occasionally observed 'an effect which looked very much like an NMR spin echo'. In spite of an apparent categorical exclusion of such effects in solids in the accepted theory, he convinced himself that such echoes would form if the pulses had a 90° phase relationship. In the phase-incoherent pulse apparatus, the random phase relationships sometimes permitted formation of such echoes. He and Powles identified the origin of this 'solid echo' in terms of magnetic dipolar interactions.¹³⁹ The solid echo would eventually form the basis for the interpretation of the response to a series of 90° pulses, thus laying the

groundwork for the theory and experimental implementation of subsequent solid-state line-narrowing methods, as we shall see in Section 8.

AMPERE

The Groupement AMPERE (Atomes et Molécules Par Etudes Radio-Électriques) was formed in 1952 to exchange information and organize magnetic resonance meetings. The AMPERE group has played an important role in sponsoring a number of major conferences and in facilitating scientific exchange among scientists, especially in eastern and western Europe, as described by Robert Blinc in his historical sketch (*The AMPERE Society and the Development of Magnetic Resonance in Eastern Europe*)

Spin Temperature and Relaxation in the Rotating Frame

The idea that a nuclear spin system in an applied magnetic field B_0 could be described in terms of a spin temperature which is different, under some circumstances, from the temperature of the lattice was understood by physicists working in NMR. Indeed, modeling the behavior of a complex system of spins coupled to one another in terms of the much more tractable thermodynamic picture has been one of the most significant developments for picturing complicated systems, understanding the behavior under pulse sequences, developing new sequences, and extracting information about the connectivity and proximity of spins in solids. In 1951, (*Pound, Robert V.: Early Days in NMR*) demonstrated that

a crystal of LiF with a ^7Li T_1 value of 5 min in a 7000 G magnetic field could be removed from the magnet, where it was adiabatically demagnetized to a low spin temperature, and then recovered its magnetization if returned to the high field in a short enough time. (T_1 was found to be about 15 s at zero field.¹⁴⁰) Purcell and Pound then constructed an apparatus in which they could move the sample to a field of about 100 G, which could be rapidly reversed in direction. By moving the LiF crystal in a few seconds from the high magnetic field to the 100 G field, reversing its polarity, and returning the sample to the high field, they observed an inverted signal, which decayed through zero with a 5-min time constant.¹⁴¹ They thus introduced to NMR the idea of a spin system at a negative (spin) temperature, a concept that would prove important in other connections.

A few years later, Alfred Redfield, during the course of a postdoctoral fellowship with Bloembergen at Harvard, embarked on a study of T_1 in aluminum and copper. Instead of using rf pulses, he and Bloembergen elected to use a continuous wave saturation method in a crossed-coil probe, a choice that was to have important consequences. Redfield soon discovered that the absorption mode signal saturated as expected with increasing rf power but the dispersion mode was much more difficult to saturate. He confirmed the result with copper. This result was in conflict with the predictions of the Bloch equations and Bloembergen's theory of relaxation. After six months of intense thinking about the problem, as described in his article (*Redfield, Alfred G.: Foundations and Structures*), Redfield developed a theory for spin temperature in the rotating frame. The theory has had a profound effect on the use of NMR in solids. During the course of this work Redfield also realized that relaxation along the effective field in the rotating frame might have a value considerably longer than T_2 , and he designated this relaxation time in the rotating frame as, $T_{1\rho}$.

Much of the development of more sophisticated ideas of spin temperature was carried out in France by Anatole Abragam, Maurice Goldman, and their co-workers. Goldman's article (*Goldman, Maurice: The Time when Spin Temperature was Hot Stuff*) provides an excellent account of the evolution of the concepts, the impact of Redfield's ideas, and their rephrasing in Abragam's *Principles of Nuclear Magnetism* (see *Abragam, Anatole: 'The Bible'*).

Meanwhile, as we have seen, Charles Slichter became one of the pioneers in NMR outside the original Harvard and Stanford laboratories when he established a strong research program in NMR at the University of Illinois. Many of the early successes in developing the concepts of scalar coupling and chemical exchange in Gutowsky's nearby laboratory involved close collaboration with Slichter, especially in providing much of the theoretical underpinning for this work. Most of Slichter's work, however, revolved around studies in solids, especially metals. In Slichter's laboratory at Illinois, experimental work was carried out to verify Redfield's theory from experiments on adiabatic demagnetization in the rotating frame (ADRF).¹⁴² This experiment set the stage for using ADRF to examine relaxation in the rotating frame and thus obtain information on motions too slow to have a measurable impact on T_1 . David Ailion, then a graduate student, developed the methods and worked out theory for interpreting the data, as described in his historical sketch (*Ailion, David C.: The First Observations of Ultraslow Motions*). He found that $T_{1\rho}$ in lithium powder was

orders of magnitude shorter than T_1 and was able to measure slow motions in solids.¹⁴³

The Overhauser Effect

Another discovery that upset the prevailing theories of thermodynamic equilibrium was the discovery by Albert Overhauser of the effects of polarization of electron spins on NMR signals as described in his historical sketch (*Overhauser, Albert W.: Dynamic Nuclear Polarization*). As Overhauser points out, a scientist's intuition suggests that a small perturbation will probably cause a small effect in a system initially at equilibrium. However, in 1953, he proposed a theory predicting that a small change in the populations of electron spins ($\sim 1\%$) in a metal would lead to a change in nuclear spin polarization by a factor of about 20! Overhauser's presentation of this work at a meeting of the American Physical Society¹⁴⁴ caused an uproar. Abragam¹⁴⁵ assessed the situation in the following words:

Overhauser's audience at the meeting of the American Physical Society—where he had (in 10 minutes) presented the calculations which had led to his amazing conclusion—was immediately split into two parts, which however overlapped: those who did not understand a single word of his demonstration and those who did not believe a single word of his conclusions. In the first row of the sceptics who did not believe his conclusions shone all the stars of magnetic resonance: Bloch and Purcell, Rabi and Ramsey. Bloembergen was of two minds and so was I.

Nevertheless, Overhauser submitted the article for publication in the *Physical Review* and (as later became apparent) Ramsey was asked to referee it. In letters quoted by Overhauser in his historical sketch, Ramsey describes his initial skepticism, his objective analysis, and his acceptance of the validity of this unexpected result.

Overhauser describes Ramsey's conclusion and the ultimate publication of the work^{144,146} as an 'intellectual' verification of the theory, but the real proof lay in experiment. Slichter, along with his student Tom Carver, set out to test the prediction by observing the ^7Li signal in metallic lithium when the conduction electron spin resonance (CESR) was saturated. They faced an experimental dilemma: for good NMR sensitivity they should work with a magnetic field of at least a few kilogauss, but then the ESR frequency would be too high to obtain adequate saturating power from the devices available at that time. They decided to work at 30.3 G, where the ^7Li resonance is at 50 kHz, with the expectation that a strongly enhanced ^7Li signal would be observable even if the normal signal was not. Slichter's historical sketch describes the results:

With this arrangement we succeeded in seeing the protons in glycerin. Changing the NMR coil (the glycerin sample was much bigger than the Li sample), Tom Carver tuned up the CESR oscillator, then turned it off to balance the NMR bridge. I was across the lab from him when I heard him shout with glee. When he had turned the CESR oscillator back on (thrown the plate voltage switch) a giant NMR line popped up on the scope. There it was—the Overhauser enhancement!

The theory and experimental verification of the Overhauser effect made a major contribution to the understanding of relaxation and thermodynamics in spin systems. It also ushered in a new area of research into 'dynamic nuclear polarization' (DNP). In addition to the substantial signal enhancements

available from DNP, there is also high spatial selectivity since only those nuclear spins reasonably proximate to an electron are affected. DNP was soon found not to be restricted to metals with conduction electrons. In free radicals and paramagnetic ions, magnetic dipolar and/or scalar coupling interactions serve as the mechanism coupling the nuclear and electron spins. Studies were carried out with F centers and solids doped with paramagnetic impurities such as free radicals. In the liquid state also, large DNP effects in solutions containing small amounts of free radicals were observed, for example by Richards et al.^{147,148,149} Besides demonstrating signal enhancements of the order of 100, they also showed that it may be possible to obtain internuclear distances between interacting molecules from the NMR signal.

BRITISH RADIO SPECTROSCOPY GROUP (BRSG)

In 1956, E. R. Andrew organized a meeting at the University College of North Wales, Bangor, to discuss the rapid progress being made in various branches of radiofrequency spectroscopy. Out of this meeting grew the informal BRSG, which has subsequently organized a number of meetings (nearly two per year on average), usually at various locations in Britain that constitute centers of relevant research activity. 'Radio Spectroscopy' has been broadly defined to include not only NMR, but EPR, NQR, far-infrared lasers, molecular beams, and related fields. Each meeting, organized independently and on a financially self-sufficient basis normally runs about two days, with invited talks, posters, and laboratory visits. Participants usually come from across Europe as well as from North America. Raymond Andrew's historical sketch (*Spinning the Spins: A lifetime in NMR*) provides additional comments on the BRSG.

In 1955, Ionel Solomon, during a stay at Harvard, developed a general theory for changes in the intensity of NMR lines in a two-spin system when one of the spins is subject to a perturbing rf field. Solomon initially treated the case of purely mutual dipolar relaxation between the spins,¹⁵⁰ and then in collaboration with Bloembergen he extended the treatment to scalar coupling as well.¹⁵¹ The theory took into account a rotational correlation time τ_c for dipolar relaxation and a correlation time for exchange τ_e that modulates the scalar coupling, and demonstrated that for short τ_c values the *nuclear Overhauser effect*, as the intensity change was called, ranges from $+\frac{1}{2}$ for purely dipolar relaxation to -1 for pure scalar relaxation. Experimental confirmation was obtained in the study of HF, where chemical exchange modulates the scalar coupling and can be controlled to modulate the importance of the two factors.

Application of the nuclear Overhauser effect was neglected for a decade but, as we shall see in Sections 6 and 11, its revival by chemists made it one of the most important tools available for elucidating the detailed molecular structure and conformation of biopolymers.

Some Early Studies of NMR in Solids

As we saw in Section 2, solids provided fertile ground for NMR investigations in the early years when magnet

homogeneity was rarely a limitation in studying their broad lines. Gutowsky and Pake had shown in 1948 the narrowing of the proton NMR line in ammonium salts, as increasing temperature permitted the onset of internal rotation. Later Powles and Gutowsky discovered the role of tunneling,¹⁵² an effect that was to be studied in much more detail in later years as described in Stanley Clough's historical sketch (*Clough, Stanley: NMR and Quantum Tunneling Rotation*). NMR was recognized as a very useful tool in investigating such processes as well as other phase changes. Molecules such as benzene and cyclohexane (which are nonpolar) along with nonpolar polymers could not be studied by dielectric loss methods, but NMR clearly demonstrated phase changes and internal motions (see *Powles, Jack: Reminiscences of the Early Days of NMR*).

These observations invariably showed that the second moment of the line was apparently reduced as the line narrowed, but Van Vleck had shown theoretically that the second moment of an NMR line is invariant even though the shape and width at halfheight might be changed by altering conditions such as the temperature. At the University of Wales, Raymond Andrew speculated that the molecular motion responsible for narrowing the line generated weak, unobservable satellites in the wings of the line. In an attempt to simulate the phenomenon in a way that would make the satellites observable, Andrew decided to rotate the sample to generate a coherent motion at a single frequency. Andrew and his co-workers chose to study the ^{23}Na NMR in a single crystal of sodium chloride, which has cubic symmetry and a modest linewidth (about 833 Hz) arising from weak dipolar interactions. They spun the crystal at speeds up to 800 Hz about an axis perpendicular to the direction of the magnetic field and recorded the ^{23}Na NMR derivative absorption spectrum (as shown in Figure 29) as a function of the spinning speed. Line-narrowing and the appearance of spinning sidebands could be clearly observed at and above spinning speeds of about 500 Hz, and at 800 Hz the central component had narrowed to about half its static width of 833 Hz. This experiment, reported in 1958,¹⁵³ demonstrated the motional narrowing effects when the spinning speed is comparable with the static linewidth, confirmed the invariance of the second moment with respect to rotation, and exhibited the appearance of the spinning sidebands separated by multiples of the spinning frequency.

Analysis of the theory showed that sufficiently rapid rotation about an axis inclined at an angle α to the magnetic field should narrow the central component by a factor $-\frac{1}{2}(3 \cos^2 \alpha - 1)$. For $\alpha = 90^\circ$, the factor is $\frac{1}{2}$ as had been observed. However, Andrew recognized that for $\alpha = 54^\circ 44'$, $\cos^2 \alpha = \frac{1}{3}$, and the dipolar interaction should vanish. Andrew, Bradbury, and Eades¹⁵⁴ extended their study by varying α from 50° to 100° and found the expected narrowing, as illustrated in Figure 30. (The residual 200 Hz width was attributed to quadrupolar interactions because of an imperfect cubic crystal.) Meanwhile, Irving Lowe had developed a similar approach.¹⁵⁵ We shall defer further discussion of sample spinning to Section 8 where we integrate these techniques with others that were introduced later to narrow lines in solids.

The study of hydrogen adsorbed on metals or combined to form metal hydrides became an important area of research. For example, Richard Norberg, both as a student with Slichter and much later as a faculty member at Washington University, studied hydrogen in palladium¹⁵⁶ and various isotopes of

Figure 29 The first published results of solid sample spinning. ^{23}Na NMR (first derivative of the absorption mode) from a single crystal of NaCl rotated about an axis perpendicular to the magnetic field direction.¹⁵³ (Reproduced by permission of Macmillan Magazines Ltd)

Figure 30 Variation of the linewidth of the ^{23}Na resonance in an NaCl crystal rotated about an axis inclined at an angle α to the magnetic field. The solid line is derived theoretically for a dipolar interaction, while the experimental data points are shown for rotation at 800 revolutions per second.¹⁵⁴ (Reproduced by permission of Macmillan Magazines Ltd)

hydrogen adsorbed on silicon semiconductors.¹⁵⁷ Likewise, Robert Cotts studied the diffusion of hydrogen in niobium hydrides and discovered restricted hydrogen-atom diffusion among the small particles,^{158,159} a solid-state analog of Woessner's and Stejskal's work described previously. The historical sketches by Norberg (*Norberg, Richard E.: NMR in Urbana and St. Louis*) and Cotts (*Cotts, Robert M.: Historical Recollections*) provide further details on these and other related investigations.

As described in the previous section, Slichter had used a clever method to measure the Overhauser effect in ^7Li . He and Schumacher employed a similar method to measure the Pauli susceptibility of electrons in sodium by measuring the conduction electron spin resonance and the nuclear resonance of ^{23}Na with the same apparatus and frequency but at very different magnetic field strengths.¹⁶⁰ Later, as his colleagues at Illinois, Bardeen, Cooper, and Schrieffer, were developing their famous (BCS) theory of superconductivity, Slichter and Hebel made critical NMR measurements.¹⁶¹ Their work, in conjunction with ultrasonic measurements, confirmed electron pairing, the basic aspect of the BCS theory.

New Perspectives on Relaxation

The BPP theory had provided the basic framework for understanding the relationship between relaxation rates and molecular motion. In some systems, however, additional factors had to be considered. For example, Lipsicas and Bloom¹⁶² found that an anomalous temperature dependence in T_1 for hydrogen gas resulted from differences in anisotropic effects in collisions between two *ortho*-hydrogen molecules and one *ortho* and one *para* molecule. Meanwhile, Streever and Carr¹⁶³ studied spin-lattice relaxation in ^{129}Xe , which has a spin of $\frac{1}{2}$, in both gas and liquid, and found that the measured T_1 values under a variety of conditions were much shorter than would be expected from intermolecular magnetic dipole interaction, presumably as a result of collisional distortions. In this work they recognized the extreme sensitivity of the ^{129}Xe resonance frequency to environmental perturbations, a feature that has recently been exploited in materials science, as mentioned later in Section 15.

In 1962, Donald Woessner (*Woessner, Donald E.: In a Maze in NMR*) extended the BPP theory to situations in which molecules in liquids tumble anisotropically.¹⁶⁴ Less well known is a similar paper by Hiroshi Shimizu at the same time,¹⁶⁵ as discussed in more detail by Yoji Arata in his historical sketch (*Arata, Yoji: Early Days of NMR in Japan*). Later, Woessner used his new formalism to treat the relaxation of molecules such as water that have preferential orientation or undergo anisotropic reorientation on surfaces. This work provided an understanding of the NMR properties of small molecules adsorbed on zeolites and clays, an area that became important in exploration for petroleum and also provided some of the underpinnings for explaining NMR linewidths in anisotropic biological materials, such as cells and tissue.

In 1961, Gutowsky, Lawrenson, and Shimomura¹⁶⁶ observed an unexpectedly short T_1 value for ^{19}F in a Freon gas and recognized the importance of the spin-rotation interaction as a mechanism of relaxation for some nuclei in molecules in the gas phase. In 1963, Hubbard¹⁶⁷ developed the theory of spin-rotation relaxation for liquids in terms of Brownian motion.

Measurement of Static Nuclear Susceptibility

As noted in Section 1.3, it is possible (but only with great difficulty) to measure the small static nuclear susceptibility in the presence of the much larger diamagnetic susceptibility from the electrons in the molecule being studied. Indeed, in

1937, Lasarew and Schubnikow made such a measurement in solid hydrogen at 2 K where the more favorable Boltzmann distribution enhanced the value of the nuclear susceptibility.

In 1955, Evans¹⁶⁸ developed an interesting method for measuring the static nuclear susceptibility at room temperature. Although it has never become important in any practical sense, the idea is worth reviewing here. Evans used an experimental arrangement as sketched in Figure 31, where two thin-walled glass sample tubes about 1 mm in diameter, each containing a sample of solid hexaethylbenzene, are suspended from a 20- μ m diameter quartz fiber, which is part of a sensitive torsion balance, in an inhomogeneous magnetic field. With the system at equilibrium, radiofrequency energy is applied over a broad band (obtained by sweeping the oscillator frequency over a range of 5%–10%) in order to saturate the nuclear spin system in the highly inhomogeneous magnetic field and thus reduce the nuclear susceptibility to zero. Although this represents a change of only about 0.05% in the overall susceptibility of the sample, a clear deflection, as shown in Figure 31, is obtained when the radiofrequency is centered at resonance, i.e. 30 MHz. Evans pointed out that the sensitivity of the method was comparable with standard NMR in 1955 (both requiring about 15 mg of sample), but that the susceptibility measurement was unlikely to have practical application since the resolution is extremely low.

NMR IN CHEMISTRY COMES OF AGE

By 1960 NMR had been established as a valuable method for chemical analysis and for the structure elucidation of organic molecules. It was clear that NMR provided key information that could often be interpreted more readily and unambiguously than other analytical data, such as infrared (IR) spectroscopy. Yet, NMR remained a technique that was carried out only by specialists who could master the idiosyncrasies of the large and complicated instruments needed. Although major improvements had been made in providing commercial spectrometers that were reasonably stable and were capable of adequate resolution for most chemical problems, as discussed in Section 3, the resultant instruments were still large and unwieldy. A ^1H resonance frequency of 60 MHz had become the standard, and behind the scenes at Varian, magnet designers were pushing the existing magnet technology as far as possible to create a 100 MHz instrument.

The most significant obstacle to a real widespread acceptance of NMR was the fact that each spectrum had to be individually calibrated and even then was not very reliable, making duplication of most data essential. The basic problem was that frequencies could be generated precisely and reproducibly with crystal-controlled oscillators, but the magnetic field stability (even with a 'super stabilizer') was not very good. Thus an NMR scan covered a range of field strength that was not known precisely.

The A-60: A 'Mass Market' for NMR

In 1956, Russell Varian had advanced the idea of using an NMR line as a control in a feedback circuit to stabilize the field/frequency relationship.⁶⁴ Eventually, a number of related schemes were developed independently for achieving

Figure 31 Top: schematic diagram of the apparatus used to observe NMR via change in the bulk magnetic susceptibility of the sample. Bottom: response as a resonant rf field is turned on to saturate the nuclear spin system¹⁶⁸ (Redrawn by permission of Taylor and Francis)

field/frequency stability that utilized an NMR line in either the sample being studied (an *internal lock*) or in a different sample (an *external lock*), and these played very important roles in the advance of numerous NMR techniques. Baker and Burd had pioneered the use of a second sample to obtain an external lock,¹⁶⁹ while Primas¹⁷⁰ had implemented the first internal lock based on an error signal from the rf dispersion mode. In this arrangement, as well as in a modification developed by Freeman and Whiffen,¹⁷¹ an audiofrequency sideband was used to scan the spectrum.

The first commercial use of a field/frequency lock was in the Varian A-60 high-resolution spectrometer for studying proton NMR at 60 MHz. The 'nuclear sideband oscillator', which

provided an external lock via a water sample in the probe, was based on Varian's early idea as implemented by Wes Anderson.¹⁷² With this circuitry, highly reproducible scans became routine. Shoolery describes the initial operation of the A-60 in these words:

The final test of the prototype, introduced at the 1961 Pittsburgh Conference, is a particularly happy memory. I put a sample into the instrument, adjusted the resolution, and ran a spectrum on the precalibrated chart. It was perfect. But could the A-60 reproduce a spectrum with the fingerprint quality of the IR? I moved the pen back and restarted the scan. Momentarily distracted, I looked back and saw only one line on the chart. 'Why didn't the second scan run?' I asked. The answer came back, 'It did'. Amazed, I returned the pen three more times. The five spectra were a single trace on the paper. At that instant, I knew that organic chemistry would never be the same.

But the A-60 represented more than the introduction of a field/frequency lock. The whole instrument was designed specifically for chemists with the objective of structure elucidation of organic compounds. As illustrated in Figure 32, the 2.5 ton magnet with 12-inch diameter pole pieces was replaced by a much smaller 6-inch magnet, and the magnet power supply and water cooling units were reduced in size and placed in the same case. The large 'console' with its multitude of components became a slim unit with a flatbed recorder for producing the spectra on large precalibrated chart paper. An integrator was provided for measuring areas under the spectral peaks. For the first time, an NMR spectrometer had the look and feel of other then common analytical instruments such as infrared and ultraviolet spectrometers. This development was the culmination of a three-year development effort called Project ASP (for 'as soon as possible'). Emery Rogers (*Rogers, Emery H.: Remembrance of NMR Things Past*) describes the genesis of the project in these words:

One day in 1957, Jim Shoolery and I visited the laboratories of a prominent East Coast chemical company. We took silent note of a wall placard which proudly proclaimed that Infrared Spectroscopy was the single most definitive analytical technique in existence. On the flight back to California, we were resolutely inspired to generate specifications for what would eventually become the widely successful A-60 High-Resolution NMR Spectrometer.

From its introduction in 1961, the A-60 had a tremendous impact on the development of NMR applications, particularly in organic chemistry. Eventually a model A-56/60 also became available for observation of both ¹⁹F and ¹H, and various improvements in the circuitry were made. Over 1000 instruments of the A-60 type were sold before it and its modified versions eventually gave way to solid-state, permanent magnet instruments.

With preprinted spectral charts available, chemists were forced to standardize the mode of presentation of NMR data. In the earliest chemical studies, the direction of field sweep and its recording were dependent on the investigator's whim. Largely as a result of practice from the Varian Applab, a low-to-high field sweep from left to right on the chart had become the de facto standard. However, while it was recognized very early on that an internal reference compound dissolved in the sample of interest was necessary for the precise measurement of chemical shifts, the choice of compound was quite variable until George Tiers¹⁷³ introduced tetramethylsilane (TMS) as an 'ideal' internal reference compound. The use of TMS caught on rapidly and the A-60 charts were based on TMS as the reference.

Unfortunately, Tiers coupled the introduction of TMS with the proposal for a new scale, the τ scale, in which the TMS reference was designated as exactly 10 ppm rather than 0 ppm, as commonly used for any other reference compound. Students and newcomers to NMR were confused by the two chemical shift scales, as advocates and opponents of ' τ -values' forcefully articulated their positions at NMR conferences. As Shoolery mentions in his historical sketch (*Shoolery, James N.: High-Resolution NMR: A Dream Come True*), he was instrumental in designing the A-60 chart to indicate TMS as 0 ppm and in publishing a large compendium of spectra (the 'Varian Catalog'¹⁷⁴) in which TMS had a $\delta = 0$ value. Although the τ scale enjoyed considerable popularity for several years and became the basis of tables in several widely read NMR books, it gradually faded from use. For example, Jackman's influential book,¹⁷⁵ published in 1959, used and advocated the τ scale, while the second edition¹⁷⁶ published 10 years later converted entirely to the δ scale. One factor that probably contributed eventually to the demise of the τ scale was the increased study of nuclei other than hydrogen, for each of which a reference scale was developed with a reference compound at $\delta = 0$. Not until the early 1970s was international agreement finally formalized through recommendations by the International Union of Pure and Applied Chemistry to use TMS as a reference at $\delta = 0$.^{177,178}

The Varian *High Resolution NMR Spectra Catalog* provided a compilation of 368 60 MHz spectra, together with a list of chemical shifts and assignments to individual protons. This catalog (which was expanded in 1963 to comprise a total of 700 spectra) provided simple, diversified, and compelling examples of the application of NMR throughout organic chemistry. A typical page is shown in Figure 33. It became a major resource to the thousands of organic chemists who now found that obtaining and interpreting NMR spectra was within their grasp.

Time Averaging

Although the A-60 brought NMR to almost every chemistry laboratory as a standard analytical method, it did not solve the problem of the low sensitivity of NMR relative to other spectroscopic techniques. The sensitivity specification for the A-60 called for a signal-to-noise ratio of six for the strongest peak of the methylene quartet in a sample of ethylbenzene at a concentration of 1% by volume in a solvent such as CCl₄ or (later) CDCl₃. (As is pointed out later, this is about three orders of magnitude lower than modern high field instruments provide.) Although this sensitivity permitted practical use of samples of about 0.1–0.2 M, many organic and especially biochemical applications required lower concentrations. Nuclei with sensitivity much less than that for ¹H and/or with low natural abundance could be studied only as neat liquids or in very concentrated solution, and even then the results were usually quite poor.

A method to improve the signal-to-noise ratio became available as NMR spectroscopists realized that the coherent addition of signals from repeated scans could result in substantial enhancement. At least four independent and concurrent efforts resulted in publications in 1963. At Berkeley, Mel Klein adapted a multichannel pulse height analyzer (commonly used in studies of high-energy radiation)

THE EXPERIMENTAL NMR CONFERENCES: THE ENC AND THE EENC

NMR results have been presented at many scientific meetings. Some involve small, select groups, such as the Gordon Conferences on Magnetic Resonance or specialized symposia, while others are part of large national or international conferences of physics or chemistry societies. But the ENC, during its 35 annual meetings, has assumed a special place in which experimental NMR methods (not applications of NMR to specific problems) are emphasized. In a recent article entitled 'ENC, A Motor of Progress in NMR'¹⁷⁸ Nobel Laureate Richard Ernst says:

Each ENC is a landmark, an hour of truth where success or failure of the previous twelve months of intense research becomes evident. Indeed from 1964 to very recently, I was working and living truly from ENC to ENC, having only one thought in mind: to be properly prepared with a new experiment or a new revealing insight to be presented at the next conference. I think it is important in the unstructured life of a scientist to have these regular caesuras to account for one's achievements.

These conferences evolved from a small, informal, one-day meeting in June 1960 at the Standard Oil Company (Ohio) Research Laboratories near Cleveland, OH. The meeting was organized by Bill Ritchey, SOHIO's resident NMR spectroscopist, who issued invitations to a number of NMR workers drawn primarily from the northeast quadrant of the United States, plus a few westerners from Varian's Palo Alto facility.

Some 42 active NMR practitioners gathered to discuss problems of the still fledgling field of practical, applied NMR spectroscopy, to hear Varian's Wayne Lockhart, Forrest Nelson, and Cappy Joller talk about trouble-shooting, shimming, and magnet cycling. There followed discussions on instrument operation (chaired by George Slomp of the Upjohn Company) and instrument accessories (led by Paul Bender of the University of Wisconsin). There was also a demonstration of Varian's new electric field shim device, the first such accessory commercially available. The meeting was a spectacular success, the few dozen early applied NMR types deriving much benefit from huddling together for comfort against the many vagaries of coaxing 40 and 60 MHz continuous wave spectrometers, with unlocked, temperature-uncontrolled, iron core magnets, into producing useful data on real molecules.

The enthusiasm generated by this meeting engendered an invitation from the Mellon Institute in Pittsburgh, PA, to hold a gathering the following year. The 'Second Conference on Experimental Aspects of NMR Spectroscopy' met in the elegant venue of the Mellon Institute on February 24–25, 1961. The timing was chosen, Pittsburgh winter weather notwithstanding, so that attendees could avail themselves of the large and important Pittsburgh Conference on Analytical Chemistry and Applied Spec-

troscopy, held in a downtown Pittsburgh hotel the following week.

This conference drew 118 attendees for a two-day immersion in a wide variety of topics and the donut-filling coffee breaks which were to become an integral part of this still small and informal 'group therapy' type of gathering. Scheduled topics included adjustment of field shape and homogeneity, measurement of rf field strength, dispersion mode spectra, quantitative aspects, survey of typical spectrometer performance, spin decoupling, and standards and referencing. In addition to these scheduled presentations and panel discussions, there was a most important development at a banquet concluding the meeting, viz. the unveiling of the brand new Varian Model A-60 NMR spectrometer.

The success of the 1961 meeting led to the continuation of these conferences on an annual basis. The conferences of 1962–70 were also held at the Mellon Institute. Space will not permit a detailed description of each of these conferences, the above descriptions of the first two meetings sufficing to convey the distance the field has come, and perhaps the feeling of community and enthusiasm which prevailed then and which to a remarkable extent remains today.

The fourth conference in 1963 had the impressive title 'Omnibus Conference on Experimental Aspects of NMR Spectroscopy', with the acronym *4th OCEANS*, but the following year the conference became known by the more manageable *ENC*. In 1970, it was recognized that the growth of the field and the demands for attendance had outgrown the cozy, familiar confines of the Mellon Institute, and these conferences moved elsewhere. The 1971 meeting was held in Gainesville, FL, and in 1972, the 13th ENC was held at the Asilomar Conference Center in Pacific Grove (Monterey), CA. This move met with widespread approval and a new pattern for the ENCs was immediately established: from that time onward, the meeting would alternate between sites in the eastern part of the country (very broadly defined) and a western location, Asilomar. Even that rather large venue is now becoming strained, with upwards of 1500 attendees.

While technically an American meeting, the ENC has always had a large number of international attendees and invited speakers. In 1974, following the suggestion by one of those attendees, Ed Randall, the successful format was transplanted to Canterbury, England, where the first European ENC (EENC) was held. A small 'junta', consisting of Ray Freeman, Pierre Servoz-Gavin, and Dieter Ziessow, guided the early development of the EENC with the same informality, ambiance, and emphasis on instrumentation and techniques as its American counterpart. Biennial meetings have been held in 11 countries throughout continental Europe, alternating with the Royal Society of Chemistry's international NMR meetings held in Britain in the intervening years.

to time-average NMR signals. Klein and Barton described the theory of time averaging in some detail, but their article submitted in July 1962 was not published until July 1963.¹⁷⁹

Meanwhile, at Harvard, Oleg Jardetzky was looking for a method to study biochemical materials at low concentration. He interfaced a commercial time-averaging device produced by the Mnemotron Corporation to a Varian 4300-B 60 MHz spectrometer, primarily for physiological measurements. The Mnemotron Model 400 Computer of Average Transients (CAT) permitted acquisition of 400 channels of data. The paper in *Nature* by Jardetzky, Wade, and Fischer¹⁸⁰ in January 1963 was the first published use of time averaging for NMR. The terminology 'CAT' stuck, even when other time-averaging computers were developed, and is probably the first widely used acronym in NMR—the forerunner of many hundreds of others used to describe a multitude of different techniques.

The field/frequency control of the A-60 lent itself to the use of time averaging. During the summer of 1962, Leland Allen of Princeton University visited the Varian Applab and, as described by Roy Johnson (*Johnson, LeRoy F.: My Early Days in NMR Spectroscopy*), Allen and Johnson interfaced the CAT-400 to the A-60 and achieved sensitivity improvement of as much as a factor of 50 with 2500 repetitions of the spectral scan.¹⁸¹ Back at Princeton, Allen reported his success and Laszlo and Schleyer quickly duplicated the Allen–Johnson setup and applied the method to the measurement of ¹³C satellites in order to measure coupling constants in a set of cycloalkenes.¹⁸² Varian developed an improved version of the CAT which had 1024 digital channels and could be triggered by an A-60 scan, and in later years Fabritek and others developed time-averaging computers with up to 4096 channels.

Structure Elucidation by NMR

With the theory of NMR in liquids now quite well understood and sufficient data available from model compounds, chemists (especially the vast number of organic chemists dealing with synthesis and with structure elucidation of natural products) were finally in a position to make routine NMR measurements. The simplicity in interpreting the proton NMR spectrum, as compared with infrared spectra, made NMR very attractive for a generation of chemists and the instrumentation had developed to the state where it was generally reliable and could be used by nonspecialists to obtain readily reproducible data. Applications quickly proliferated. Jackman and Sternhell noted in their book¹⁷⁶ published in 1969 that there were well over 6000 literature references to NMR, compared with about 400 a decade earlier. The vast majority related to the use of NMR in organic structure elucidation.

At 60 MHz, the NMR spectra of many of the protons of alicyclic systems such as steroids were a featureless blur, but the methyl groups were readily recognizable even at 40 MHz, as discussed in Section 3.4. Extensive studies of the effects of small structural variations upon the precise shift of these groups enabled steroid chemists to obtain a remarkable amount of information from the chemical shifts of angular methyl groups in unknown compounds. In 1960, heterocycles did not appear to offer fertile ground for NMR analysis because of the relatively few protons in their rings. However, by the end of the decade, so much useful information had been acquired that a 500 page book entitled *NMR Spectra of Simple Heterocycles* was devoted to the subject.¹⁸³

With a larger collection of NMR data available and more experience in spectral interpretation, chemists were able to draw subtler inferences from observed chemical shifts, coupled with general chemical knowledge. One example of the type of study possible with even a simple spectrometer can be found in the study of an alkaloid, amaryllisine.¹⁸⁴ The A-60 spectrum shown in Figure 34 reveals the presence of three methoxyl groups, an isolated methylene group in an asymmetric environment, and two olefinic protons with one being coupled to a 'carbinol' proton. These features may be fitted readily into one of the structural frameworks known in this class of alkaloid, with the exact substitution of the aromatic system still unresolved. The position of the lone hydrogen on the aromatic ring can be fixed by comparing the chemical shifts of the parent alkaloid and its dihydro derivative, for reduction of the double bond results in an upfield shift of 0.18 ppm of the nearby aromatic proton. Finally, comparison of the aromatic proton shifts of the alkaloid in neutral and basic solutions shows that conversion to the phenolic anion shifts the aromatic proton 0.23 ppm upfield, which is characteristic of a proton *ortho* to the phenol.

This study is illustrative of many which extracted more structural details from the spectra than available at first glance. Comparison of the chemical shifts of the *N*-methyl groups of basic nitrogen in neutral solvents and in trifluoroacetic acid allowed them to be distinguished from those on neutral materials. The problem of assigning the substitution patterns in the methoxy–hydroxy aromatic rings common in natural products was approached by comparing the chemical shifts in neutral and basic solutions. NMR provided key data, but it was the experience of the organic chemist that drove the interpretation of the data. In the 1960s a number of books showed how NMR could be used in structure elucidation, either in its own right or in combination with infrared and mass spectrometry. Emery Rogers' goal (quoted above) of making NMR an analytical method on a par with infrared spectroscopy had been achieved.

NMR of Soluble Polymers

As Frank Bovey points out in his historical sketch (*Bovey, Frank A.: NMR of Polymers*)

When polymers in solution were first observed by high-resolution NMR some 30 years ago, almost nothing was known about the subject. . . . There was in fact somewhat the same feeling about solution spectra as about solid state spectra—namely that they would be too broad and too complicated to be of any interest for the determination of structure. Happily, when the experiment was actually tried this proved not to be the case, and the rest is history.

In the absence of cross-linking, internal flexibility in long polymer chains provided the motional narrowing needed to generate real high-resolution spectra, from which chemical shifts and coupling constants could be derived even at 60 MHz. The principal advantage provided by NMR in polymer analysis was the determination of stereoregularity.

By this time, chemists had begun to understand the role of asymmetric centers in influencing NMR spectra. The paper by Waugh and Cotton¹⁸⁵ and papers by Roberts and others showed that methylene protons can be rendered observably nonequivalent in chemical shift if they are in an asymmetric

Figure 32 Top: the Varian HR-60 spectrometer. Bottom: the Varian A-60 spectrometer

environment. In fact, a range of examples from NMR contributed greatly toward clarifying for most chemists the consequences of molecular symmetry and asymmetry.

In polymers, extensive work by Bovey and others showed that these concepts could be readily applied to groups of two, three, or more repeating functional groups (dyads, triads, etc.). Bovey's historical sketch (*Bovey, Frank A.: NMR of Polymers*) provides a lucid treatment of the reasoning and gives examples of applications to polymers of varying tacticity. Later, such studies were extended to ^{13}C NMR as suitable techniques became available for studying this nucleus, and theoretical treatments provided a better understanding of the origin of chemical shifts in various polymers (see *Ando, Isao: Structures and Electronic States of Polymers as Studied by High-Resolution NMR Spectroscopy Combined with Quantum Chemistry*).

NMR of Paramagnetic Systems

While the vast majority of NMR studies in the late 1950s and the 1960s were devoted to diamagnetic organic compounds, several physical chemists began the exploration of paramagnetic systems by NMR, a field of study that was

eventually to have considerable impact on NMR investigations of organic compounds and biopolymers.

Since the magnetic moment of an unpaired electron is about 10^3 times as large as that of a typical nucleus, the interaction between the paramagnetic center and nuclear magnetic moments in the same molecule (or sometimes in nearby molecules) can give rise to large chemical shifts and/or to a decrease in relaxation times resulting in the broadening of spectral lines.

Observations of the effects on NMR spectra of electrolyte solutions containing paramagnetic species date back to the 1950 studies by Bloembergen and Dickinson.¹⁸⁶ In addition, Phillips et al.¹⁸⁷ in 1957 observed 'anomalous' shifts in the proton spectra of *n*-propanol and *n*-hexanol in the presence of paramagnetic ions such as Mn^{2+} and Co^{2+} .

The first reported NMR spectrum of an intact paramagnetic molecule in solution came in 1957 from McConnell and Holm¹⁸⁸ who observed an 'unusual' proton NMR shift in the paramagnetic sandwich compound nickelocene [dicyclopentadienylnickel, $\text{Ni}(\text{C}_5\text{H}_5)_2$], both as a polycrystalline solid and in toluene solution at room temperature. In toluene, the proton resonance of nickelocene was a line about 300 Hz wide and about 300 ppm more shielded than the toluene resonance. (Only a single broad line for toluene was observed at the

operating frequency of 16 MHz). In solid polycrystalline nickelocene, the shift to higher field was over 320 ppm relative to the proton resonance of water containing 0.05 wt% of Mn^{2+} . Similar large shifts, but to lower field, were observed a few months later by McConnell and Holm¹⁸⁹ in $\text{V}(\text{C}_5\text{H}_5)_2$ and $\text{Cr}(\text{C}_5\text{H}_5)_2$ under conditions identical to those for the nickel compound. In 1960, Phillips and Benson¹⁹⁰ observed both high- and low-field shifts in the proton magnetic resonance spectra of solutions of nickel aminotroponeimineates. The proton relaxation times in these compounds are sufficiently long to allow proton spin–spin interactions of about 6–12 Hz to be resolved. The spin–spin couplings, along with the intensities of the spectral lines, permitted unique assignments of the observed proton resonances to various nonequivalent sets of protons of each chelate.

The large differences in the nuclear shieldings observed in such cases were explained quantitatively in 1958 by McConnell and Robertson¹⁹¹ in terms of an isotropic contact interaction between the nuclei and the unpaired spin density produced in the ligand molecule by the paramagnetic metal atom to which it is bonded.

The large paramagnetic shifts usually generate first-order spectra, which were exploited as an important tool during the 1960s in transition metal chemistry. Contact shifts have thus been reported for the ligand atom nuclei of many transition metals, especially cobalt(II) and nickel(II) which usually display sharp resonances. Studies related to electron distribution, bonding, and structure of metal complexes, including structural and spin equilibria and optical isomerism, have been undertaken extensively. Investigations on ion-pair formation in solution, solvation phenomena, kinetics of chemical exchange processes, electron and proton transfer studies have also been carried out.

Large values of the hyperfine interaction constant are expected to produce line-broadening in the NMR spectra, but species with large values of the hyperfine interaction constant may exhibit sharp lines if the correlation time for the contact interaction is short. This can happen from rapid electron relaxation and/or rapid exchange, as has been demonstrated for the case of electron transfer between diamagnetic and paramagnetic species by DeBoer and MacLean.¹⁹² A typical

Figure 35 The ^1H NMR spectrum of the nickel(II) chelate of 1-(2-naphthylamino)-7-(2-naphthylimino)-1,3,5-cycloheptatriene in CDCl_3 .¹⁹³ (Reproduced by permission of the American Chemical Society)

early spectrum,¹⁹³ shown in Figure 35, shows 10 sharp proton resonances, four to lower field (negative spin density) and six to higher field (positive spin density). The resonances H_α , H_β , and H_γ were readily assigned to the three nonequivalent sets of protons of the seven-membered ring, and four of the seven resonances attributable to the naphthalene ring exhibited resolvable nuclear spin–spin structure.

The work on paramagnetic species not only provided valuable information in transition metal chemistry but also laid the groundwork for extension of the concepts to NMR investigations of organic structure via shift reagents.

Lanthanide Shift Reagents

During the course of investigations on the binding of cholesterol in solution with complexes of rare earth metals, Hinckley¹⁹⁴ in 1969 made one of the most valuable discoveries in organic NMR. He observed that some paramagnetic lanthanide β -diketones can be employed to induce large shifts in the NMR spectra of molecules to which they complex, thus facilitating spectral analysis by reducing complex spectra to weakly coupled spectra in which chemical nonequivalences can be readily discerned and coupling constants can be easily evaluated. His initial experiment used a dipyrindine adduct of tris(dipivalomethanato)europium(III), $\text{Eu}(\text{dpm})_3 \cdot 2\text{Py}$, with a sample of cholesterol monohydrate in CCl_4 . The key to the use of such ‘shift reagents’ is that they induce substantial paramagnetic shifts without causing relaxation that broadens lines and reduces resolution. With lanthanide shift

reagents (LSR), it became possible to obtain a wealth of useful information for fairly complex systems with even low frequency spectrometers.

In fact, the history of the use of paramagnetic ions as shift reagents can be traced back to 1960 when Lewis, Jackson, Lemons, and Taube¹⁹⁵ observed that the addition of the paramagnetic Co^{2+} ion to aqueous solutions of diamagnetic salts of Be^{2+} , Al^{3+} , and Ga^{3+} resulted in a well-resolved two-line ^{17}O NMR spectrum, one due to the water of hydration of the diamagnetic ion and the other due to solvent water which is in rapid equilibrium with the first hydration sphere of Co^{2+} and hence is shifted. Subsequently, this group observed that the rare earth dysprosium ion may be better suited as a shift reagent since it induces large ^{17}O shifts of water without significant broadening, and large proton shifts were reported for paramagnetic rare-earth acetylacetonates, tropolonates, and acetates by Eaton,¹⁹⁶ Muetterties and Wright,¹⁹⁷ and Reuben and Fiat.¹⁹⁸

Shifts from LSRs have been found to result from pseudocontact interactions which arise from direct magnetic dipole–dipole interaction between the spins of the unpaired electrons and those of the nuclei. Thus, the magnitude and sign of the LSR-induced shift at each nucleus can be related to the geometry of the molecular complex in terms of both distances and angular factors. Fortunately, many of the lanthanides have sufficiently short electron relaxation times to preclude significant magnetic dipolar relaxation and hence to retain the sharp NMR lines characteristic of most small organic molecules.

UK NMR DISCUSSION GROUP

About the same time that the ENC was formed in the United States, a group of early NMR practitioners in and near London, England, also issued a call for like-minded scientists to assemble for an informal meeting at the Northern Polytechnic, where Eric Mooney had one of the first Perkin-Elmer NMR spectrometers. Ernie Cummins, at Perkin-Elmer, was instrumental in forming the group, modelled somewhat after an infrared spectroscopy discussion group. With the enthusiasm generated by the unexpectedly large attendance (about 150), the attendees formed the UK NMR Discussion Group, which went on to hold semi-annual meetings in various parts of the United Kingdom. In the mid-1960s the Group affiliated with the Chemical Society, and under these auspices sponsored, in 1969, the first of what would become a series of International Meetings on NMR Spectroscopy.

The 26th meeting of the Group, in 1974, under Ed Randall's chairmanship, was devoted entirely to experimental aspects of NMR and included a number of participants from continental Europe. This meeting served as a model for the European ENC, which would eventually be held biennially on the continent, alternating with the International Meetings on NMR Spectroscopy of the Royal Society of Chemistry in the UK.

Many more efficient shift reagents were introduced to study a variety of problems. The use of anhydrous lanthanide complexes of dpm instead of the pyridine adduct was proposed by Sanders and Williams,¹⁹⁹ who employed $\text{Eu}(\text{dpm})_3$ for

Figure 36 The 100 MHz ^1H NMR spectrum of *n*-hexanol plus $\text{Eu}(\text{dpm})_3$ in CCl_4 .¹⁹⁹ (Reproduced by permission of the Royal Society of Chemistry)

obtaining a well-resolved first-order spectrum of *n*-hexanol at 100 MHz, as shown in Figure 36. This shift reagent increased selective shifts by a factor of about four in cholesterol under conditions comparable with Hinckley's early experiment. In 1971, Rondeau and Sievers²⁰⁰ reported that the lanthanide tris-chelates of 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedione [$\text{H}(\text{fod})$] were new 'superior' shift reagents for NMR spectral simplifications. Their effectiveness was especially pronounced for classes of compounds such as ethers that are rather weak donors. The complexes with fod are also considerably more soluble in organic solvents than those with dpm.

In 1970, Whitesides and Lewis²⁰¹ reported the first chiral LSR for the study of enantiomers. In this study, lanthanide tris-chelates with the ligand 3-(*t*-butylhydroxymethylene)-*d*-camphor were employed. Subsequently more effective chiral shift reagents were added to the list, and other types of LSRs such as binuclear lanthanide(II)–silver(I) complexes and water-soluble lanthanide complexes were introduced. Effective shift reagents soon became available for most classes of compounds.

The field of shift reagents experienced an explosive growth during the 1970s. As higher field NMR spectrometers became widely available, the general need for LSRs diminished but they continue to be applicable in many instances.

Isotope Effects

As improvements in magnet homogeneity and stability permitted more precise measurements of chemical shifts, NMR spectroscopists began to notice small changes on isotopic substitution. The first report of isotope effects was that of Wimet²⁰² in 1953 who found differences in the shielding of ^1H and ^2H in molecular hydrogen. However these differences were barely outside experimental error, and isotope effects attracted little attention until Tiers²⁰³ found upfield shifts in ^1H and ^{19}F resonances on substitution of a nearby hydrogen by deuterium. For example, the CF_2D group in *n*- $\text{C}_3\text{F}_7\text{D}$ was shifted by 0.60 ppm to higher field than the corresponding group in *n*- $\text{C}_3\text{F}_7\text{H}$. Later, Gutowsky Karplus, and Grant (1959) observed an upfield shift of the proton resonance in dicyanomethane by 0.003 ppm as a result of the substitution of one proton by a deuteron,²⁰⁴ and Gutowsky interpreted these isotope effects as arising from the difference in the vibrational amplitudes of hydrogen and deuterium, in accord with Ramsey's theory of the chemical shift.

Subsequent investigations by a large number of people established the general systematics of the field. The theory has been worked out in great detail, especially by Cynthia Jameson.²⁰⁵ More recently, long-range effects through as many as 12 chemical bonds in conjugated hydrocarbons have been observed for ^{13}C on deuterium substitution for hydrogen.²⁰⁶ The isotope shift of about 0.02 ppm arising from the substitution of ^{18}O for ^{16}O bonded to a phosphorus atom has been used to label individual phosphorus atoms and to investigate their fate in biochemical reactions.

Chemically Induced Dynamic Nuclear Polarization

In 1967, Ward and Lawler at Brown University observed unexpected intense ^1H NMR signals (both positive and negative) in olefins (alkenes) involved in the rapid reactions of organometallic compounds.^{207,208} Since the reaction proceeds by a free-radical mechanism, they reasoned that the intense signals must arise from interactions with the electron spins in a manner analogous to the dynamic nuclear polarization first predicted by Overhauser (see Section 4). Meanwhile Joachim Bargon, a graduate student in Darmstadt, had already observed a strong negative polarization of benzene in a polymerization reaction initiated by benzoyl peroxide.^{209,210} He and Hans Fischer coined the name Chemically Induced Dynamic Nuclear Polarization (CIDNP), a name that has persisted despite the fact that later work (principally by Closs²¹¹ and Kaptein^{212,213}) established a different mechanism for the phenomenon. Robert Kaptein's historical sketch (*Kaptein, Robert: The Early Days of CIDNP*) points out:

The first observation of CIDNP dates long before the 1967 publications. In fact, countless discoveries and rediscoveries have been made, often dismissed as artifacts. An example is that from the laboratory of Prof. Th. J. de Boer of the University of Amsterdam. NMR spectra of a cyclopropyl compound in CDCl_3 had the chloroform line in emission or absorption depending on the operator who ran the spectrum. It turned out that one operator had the habit of shaking the NMR tube before recording the spectrum, while the other had not! The slight amount of oxygen mixed in the solution oxidized the labile cyclopropyl compound, which resulted in polarized CHCl_3 as one of the products of a radical recombination reaction. Since the chloroform proton has a T_1 value of 60 s or so, it is a particularly favorable molecule in which to store nuclear polarization.

Kaptein, who was then a student with Oosterhoff at the University of Leiden, immediately followed up these reports and discovered that products from radical pair combination showed one sign of polarization, while those from radical scavenging reactions had the opposite sign. He developed a quantum mechanical theory based on radical pair interactions that accounted for these results. At the same time, Gerhard Closs at the University of Chicago developed a similar theory based on hyperfine coupling induced by singlet–triplet mixing in the photochemical reactions that he was studying. One of the triumphs of these theories was their ability to explain the observation of sign reversal within a spin-coupled multiplet, as illustrated in Figure 37.²¹⁴ CIDNP rapidly became a useful tool in studying organic reaction mechanisms initiated photochemically or by free-radical reactions, and later Kaptein developed a laser photo-CIDNP to obtain information on the sites of binding of ligands to certain proteins.^{215,216}

High-Pressure NMR

Although temperature has been exploited as a variable in NMR studies since the earliest measurements, pressure was used only sparingly in early work probably because of the complexity of apparatus needed. Nevertheless, David McCall and his colleagues at Bell Laboratories were among the early workers who measured self-diffusion by spin echo methods at pressures up to 700 bar.²¹⁷ At Illinois, Jiri Jonas began a long-term program in high-pressure NMR during the late 1960s (see *Jonas, Jiri: NMR and High Pressure*) in which he successfully made high-resolution NMR measurements, first with conventional continuous wave methods and later with early Fourier-transform techniques. He and his colleagues were able to analyze the effect of changes in viscosity on the rates of reaction without the complicating factors introduced when viscosity is altered by changing solvents. They also examined phase changes in solids and solid polymers and developed insight into the behavior of water at supercritical pressures.

Liquid Crystals

As we saw in Section 2, the earliest NMR studies clearly differentiated between studies in liquids where sharp lines permitted observation of chemical shifts and scalar couplings, and solids where these effects were obscured by broad lines but where additional information could be obtained from anisotropic quadrupolar and magnetic dipolar interactions. During the 1950s some NMR spectroscopists sought methods

Figure 38 The ^1H NMR signal from *para*-azoxyanisole in the liquid crystal phase.²¹⁹ (Reproduced by permission of the American Institute of Physics)

whereby such interactions could be observed and measured from line-frequency separations, rather than linewidths, by orienting molecules in the liquid state. Initial attempts to induce molecular orientation included the use of an electric field, the absorption of molecules in polymers with subsequent stretching, and embedding the molecules in zeolite crystal channels. The success achieved in such experiments was insufficient to make them routine techniques for the precise determination of the parameters in question.

A breakthrough was made by Saupe and Englert²¹⁸ in 1963 when they proposed the use of liquid crystals as solvents for studying the NMR spectra of small molecules. This gave birth to a new field of NMR spectroscopy of oriented molecules. Since then the field has developed rapidly, particularly for the determination of relative internuclear distances and bond angles, and has provided the only method for the direct measurement of molecular shapes in the liquid state.

The first application of NMR to liquid crystals themselves was made by Spence, Moses, and Jain²¹⁹ as early as 1953, when the proton NMR spectrum of *p,p'*-dimethoxyazoxybenzene (*p*-azoxyanisole) was observed in a nematic liquid crystalline phase. As shown in Figure 38, three broad lines were observed. The splitting pattern was initially interpreted as arising from very strong hindering of the rotations of the methyl groups or ascribed to the magnetic nonequivalence of the protons in the phenyl rings in the liquid crystal phase. Subsequently, Spence, Gutowsky, and Holm²²⁰ found that at two other magnetic fields the splittings were the same and hence concluded that the spectral features were not attributable to a chemical shift effect but could be interpreted on the basis of dipole–dipole interactions between the protons. The two extreme lines were due to aromatic protons split into the broad doublet by the *ortho* ^1H – ^1H dipolar couplings and the central line arose from the aliphatic protons.

What Saupe and Englert observed were the sharp lines arising from the protons of the small molecules dissolved in the liquid crystalline media superimposed on the broad background arising from the liquid crystal protons. The first spectrum of a molecule (benzene) dissolved in a liquid crystal solvent is shown in Figure 39. Although the linewidth was

several Hz (due to temperature gradients and instrumental effects), the lines were sharp enough to be interpreted as arising from intramolecular dipolar couplings, chemical shifts, and indirect spin–spin couplings. Values of the chemical shifts and the indirect spin–spin coupling constants derived from such spectra were shown to contain information on the anisotropic contributions of these parameters. The inverse cube dependence of the direct dipolar couplings provided a method for the precise determination of relative internuclear distances and bond angles. Saupe²²¹ developed the theory of molecular orientation in terms of the order parameter while Snyder²²² presented an alternative approach, which he also showed to be equivalent to Saupe's.

The concentration and temperature dependence of the splittings in the spectra of oriented molecules was investigated by Diehl and Khetrapal²²³ in 1967. They found that, in general, the order parameter decreases with an increase of temperature and concentration. Any contrary behavior indicates weak molecular interactions; hence the method was employed to study such interactions. Yannoni, Ceasar, and Dailey²²⁴ studied the first metallo-organic compound, the π -complex iron tricarbonyl cyclobutadiene, and showed that the four protons do not lie at the corners of a perfect square. Applications were extended to less symmetric and more complicated molecules, chemical shift anisotropies were determined, and absolute signs of indirect spin–spin couplings could also be determined in many cases.

The spectra of oriented molecules, particularly in thermotropic nematic liquid crystals, were found to be strongly coupled unless heteronuclei were involved, thus resulting in a rapid increase of spectral complexity with increase of the number of interacting nuclei. This has remained the major problem in applying these methods to more complex molecules. Over the years a number of new approaches have been introduced to simplify spectra, including the use of lyotropic liquid crystals,²²⁵ double-resonance techniques,²²⁶ multiple quantum spectroscopy,²²⁷ isotopic substitution with heteronuclear decoupling,²²⁸ the use of near magic angle spinning,²²⁹ the use of two-dimensional NMR,²³⁰ and the use of mixed liquid crystals of opposite diamagnetic anisotropies.^{231,232}

The study of ^2H NMR in liquid crystal molecules and in small molecules dissolved in liquid crystals has been pursued by a number of workers. Since the deuterium quadrupole coupling constant can often be estimated reliably, spectral splittings provide information on order parameters. For example, Figure 40 shows the ^2H NMR spectrum of *p,p'*-azoxydi(phenetol- $\alpha,\alpha,\beta,\beta,\beta$ - d_5). The two doublets arise from two types of deuteriums (CD_3 and CD_2) which have different order parameters.²³³ In Section 10, we point out the application of such local order parameters to the study of the mobility of fatty acid chains in phospholipids and biomembranes. The values of order parameters determined from the ^2H spectra have also been used to aid the analysis of the corresponding proton NMR spectra which, as we have seen, can be quite complex.

MAJOR ADVANCES IN NMR TECHNOLOGY

With NMR firmly established as an indispensable tool for chemistry during the early part of the 1960s, physicists, chemists, and instrument designers began to think about more

Figure 39 The ^1H NMR spectrum of benzene dissolved in the nematic solvent p,p' -dihexyloxyazoxyanisole.²¹⁸ (Reproduced by permission of the American Physical Society)

Figure 40 The ^2H NMR spectrum of p,p' -azoxydi(phenetol- $\alpha,\alpha,\beta,\beta,\beta$ - d_5) at 6.5 MHz in the dispersion mode.²³³ (Reproduced by permission of the American Institute of Physics)

sophisticated techniques and more powerful instruments. Two principal areas that were developed through most of this decade have had continuing impact on all subsequent NMR applications.

Nuclear magnetic double resonance (NMDR) methods became essential to the analysis of the spectra of complex molecules. Moreover, these methods could be used to follow reaction kinetics and to enhance the sensitivity of NMR spectra. The application of double resonance also provided a major advance in the development of ^{13}C NMR and in studies of other nuclei of low sensitivity.

The continuing attempt to reach higher magnetic fields led to the development of superconducting magnets of the necessary homogeneity and stability for high-resolution NMR. This enormous advance in instrumental capability continues unabated, with no end in sight.

Another factor that played an increasingly important role in the development of NMR was the entry of other instrument companies to challenge the virtual monopoly held by the pioneering Varian Associates.

Double Resonance Methods

The idea of *double* resonance, i.e., perturbing one or more particular transitions while simultaneously monitoring

a different transition, has led to many exciting developments in NMR and its applications. The first double resonance experiment was carried out by Pound²³⁴ in his early study of relaxation in ^{23}Na in solid sodium nitrate. He irradiated one line in the spectrum and observed an intensity increase in a second line, thus proving that relaxation occurred by a nuclear quadrupole interaction with the surrounding field gradient, rather than by dipolar relaxation which could be shown to result in no NMDR intensity change. Although it provided only a modest intensity change, this observation really anticipated the Overhauser effect and became the forerunner of other experiments in which intensity changes were observed.

At the other end of the scale of NMDR perturbations, Wes Anderson developed the basic theory of spin decoupling (a suggestion that he attributed to Bloch) while a graduate student at Stanford, but published the results from CERN in 1956 as part of a long paper covering many aspects of spectral analysis.²³⁵ Meanwhile, Virginia Royden, at Varian Associates, reported the first decoupling experiment²³⁶ in 1954, when she irradiated the ^{13}C in 51% enriched $^{13}\text{CH}_3\text{I}$ to decouple the ^{13}C 'satellite' lines and from the optimum decoupling frequency determined an accurate ratio of the magnetic moments of ^1H and ^{13}C , as illustrated in Figure 41. The next year Bloom and Shoolery (also at Varian) partially anticipated Anderson's paper with their theoretical treatment of the effect of a strong perturbing rf field.²³⁷ They showed that for two scalar-coupled spins separated by a large frequency relative to their coupling, the theory could be developed by transforming the problem to a frame rotating at the frequency of the perturbing field—a basic approach followed in almost all subsequent work. They found that with a sufficiently strong rf field the splitting from spin coupling can be almost completely eliminated, but that at somewhat lower field strengths the structure in the spectrum can increase in complexity. Experimental results were presented on ^{19}F and ^{31}P resonances in aqueous solutions of $\text{Na}_2\text{PO}_3\text{F}$ and found to support the theoretical predictions.

The initial double resonance experiments simply employed rf oscillators operating at the nominal frequencies of the two nuclides, with a provision for 'pulling' the perturbing oscillator to obtain the exact frequency desired. Even for the proton-proton decoupling experiments described by Anderson, two separate rf oscillators were used. Considerable simplification of the equipment and superior operation for NMDR and other NMR experiments could be achieved by the use of a lock-in detector to detect an audio modulation sideband.^{238,239} Itoh and Sato²⁴⁰ employed this method to decouple the methyl and aldehyde protons in acetaldehyde. In 1959, Ray Freeman began to study homonuclear double resonance effects by employing audio modulation methods. As he describes in his historical sketch (*Freeman, Ray: Double Resonance Methods*

Figure 41 The 30 MHz ^1H NMR spectra of CH_3I enriched to 51% in ^{13}C . Top: single resonance spectrum. Bottom: simultaneous irradiation of ^{13}C at 7.5 MHz to decouple the ^{13}C -H doublet. (Reproduced by permission of the American Physical Society)

in *High-Resolution NMR*), it was David Whiffen's insight into the difference between a magnetic field sweep and a true frequency sweep of only the observing rf that clarified important elements of the theory. Freeman applied these concepts in field-sweep and frequency-sweep decoupling.²⁴¹ Freeman also introduced an internal lock, patterned after the concept developed by Hans Primas and based on an additional modulation sideband. This stable lock permitted precise control over irradiation frequencies and permitted a range of NMDR experiments, since it is essential for slow frequency sweep NMDR.

Meanwhile, at Harvard, John Baldeschwieler was examining the theoretical basis for double resonance under a variety of experimental conditions. The review by Baldeschwieler and Randall²⁴² in 1963 was influential in pointing out both the complexities and opportunities of NMDR. This review also popularized the A{X} notation, in which the observed nucleus A is listed first and the perturbed nucleus X is given in braces.

The Chemical Applications of Double Resonance

One of the first real applications of decoupling to a chemical problem was made by Evans and Maher²⁴³ in 1961 when they studied the thallium diethyl cation. Two methyl and two methylene group resonances were observed since Tl-H couplings are quite large, but it was not clear which methyl resonance went with which methylene group. A 'selective' decoupling experiment, in which only one of the methyl groups was irradiated, provided the answer. In addition, Evans pointed out that this experiment provided a method for the determination of the relative signs of the coupling constants. This one experiment is remarkable for initiating two completely different sets of applications. First, selective decoupling was developed extensively to identify proton resonances that are coupled and thus to elucidate the structures of a vast number of organic compounds. Second, the NMDR technique rapidly became the standard method for determining the relative signs of coupling constants, a key factor in the analysis of complex spectra and in the

Figure 42 Top: field sweep 60 MHz ^1H NMR spectrum of 2-furoic acid, an example of an ABX (nearly AMX) spin system. Bottom: the X portion of the spectrum recorded with simultaneous irradiation of (a) transitions 5 and 6; (b) 7 and 8; (c) 1 and 2; and (d) 3 and 4.²⁴⁴ (Reproduced by permission of Taylor and Francis Ltd)

development of the theory of scalar coupling. Freeman and Whiffen²⁴⁴ recognized the generality of Evans's procedure and extended it to the determination of the relative signs of ^1H coupling constants in an AMX system. Figure 42 illustrates this work with the spectrum of 2-furoic acid subject to double irradiation.

When Freeman joined Varian Associates in 1961 to work with Anderson, the confluence of these two experts in NMDR was bound to produce further advances in the field. In a series of papers they worked out the optimum conditions for NMDR experiments and investigated the additional splittings sometimes observed at relatively low perturbing rf field strengths. Their systematic treatment of splittings caused by 'spin tickling' showed that unambiguous information could be extracted on energy level diagrams.^{245,246} This method became a very useful aid for the assignment of transitions for the computer analysis of strongly coupled spectra, and also picked out sub-spectra that indicated the relative signs of the coupling constants.

The reverse of the tickling experiment, usually termed internuclear double resonance (INDOR),²⁴⁷ also became quite valuable in locating weak or hidden transitions. In such experiments, the observing field is kept fixed at the peak of a chosen transition and the perturbing field is swept throughout the spectrum in order to search for the connected transition. INDOR soon assumed importance as a method for obtaining the chemical shifts for a nucleus of low sensitivity, such as ^{13}C , by observing the sensitive nucleus (usually ^1H) to which it is coupled.

Instrumentation for heteronuclear double resonance steadily improved during the 1960s with the development of more versatile spin decouplers. The 'Gyrocode' decoupler in the XL-100, introduced in 1969, was the beginning of a new, frequency-selectable rf source. Commercially available frequency synthesizers formed the rf centerpiece for multinuclear spectrometers, as we shall see in later sections.

Proton decoupling assumed a vital role in making feasible the direct observation of ^{13}C at natural abundance. Selective

Figure 43 Participants at the Second International Symposium on Magnetic Resonance, Sao Paulo, Brazil, July 1969. This meeting, organized by Leonard Reeves, E. Giesbrecht, and S. Mathias, was a forerunner of the series sponsored by the International Society of Magnetic Resonance. The formation and activities of ISMAR are described in Daniel Fiat's historical sketch (*Fiat, Daniel: The International Society of Magnetic Resonance (ISMAR). Landmarks and Highlights*)

off-resonance decoupling provided a powerful method for the analysis and assignment of individual ^{13}C resonances, but for the greatest sensitivity in simply observing a ^{13}C NMR spectrum, complete decoupling of protons throughout their spectral range provides a threefold advantage: (a) spectral simplification; (b) intensity enhancement resulting from the collapse of the multiplets; and (c) intensity increase due to the nuclear Overhauser effect (as we discuss below). A practical method for such broad-band decoupling was proposed by Ernst²⁴⁸ in 1966 and became very useful for the decoupling of weakly coupled, primarily heteronuclear, spin systems. This technique, commonly called 'noise decoupling', uses pseudorandom noise to make 180° phase changes in the perturbing rf field and hence irradiate over a broad frequency range. In his historical sketch (*Ernst, Richard R.: The Success Story of Fourier Transformation in NMR*), Ernst describes the initial experiments in these words:

The first experiments concentrated on a fluorine-proton system. The necessary binary random noise was taken initially from the even/odd character of the last digits in the Palo Alto telephone directory, modulated onto the radiofrequency carrier, and applied to the protons, observing the fluorine resonance at the same time. This led to the initial pseudonym 'phone-book resonance'. Only later was I informed by R. Whitehorn (Varian Associates)

that binary noise could be generated in a more convenient and predictable manner by shift register generators that were used from September 1965 onwards.

Noise decoupling was used largely in the form developed by Ernst, with numerous, but only slight improvements, for over 15 years. One investigator is said to have used phonograph recordings of music to generate the random noise; Beatles records were said to work particularly well. Most of the advances, however, involved the tailoring of pseudorandom noise functions to provide a broader and more nearly flat response. In the 1980s fundamental analyses of the decoupling process by Freeman²⁴⁹ and Waugh²⁵⁰ gave insight into more efficient procedures using pulse sequences, as outlined in Section 7.

In 1963, Forsén and Hoffman initiated a new application of NMDR when they investigated the transfer of polarization between two exchanging sites.²⁵¹ By saturating the nuclei at one site (or, with later technology, using a perturbing rf pulse), the equilibrium population of nuclei at that site can be disturbed, and chemical exchange causes this disturbance to affect a second site. These NMDR methods greatly extended the range that could be studied by NMDR to much slower exchange, the only limitation being the spin-lattice relaxation

times of the exchanging nuclei. With later pulse techniques and especially two-dimensional NMR methods, this type of investigation has assumed increasing importance, as we shall see in later sections.

The NOE Becomes a Useful Technique

In Section 4 we mentioned the initial studies of the nuclear Overhauser effect (NOE), in which one resonance changes intensity when another line is perturbed by an rf field. Although it lay dormant for about 10 years, the NOE rapidly developed into one of the most useful and most widely applicable of all NMR techniques in chemistry, with three distinctly different uses: (i) estimation of internuclear distances as an aid to the determination of molecular conformation; (ii) enhancement of the NMR intensity of less sensitive nuclei that are close to protons; and (iii) estimation of correlation times to clarify the motions in macromolecules.

The first publication to demonstrate the utility of the NOE in chemical structure determination was that by Anet and Bourn²⁵² in 1965, who showed that in *N,N*-dimethylformamide the assignments of the methyl groups *cis* and *trans* to the formyl proton could be made on the basis of the relative nuclear Overhauser enhancements of their resonances when the formyl proton was irradiated. For two protons in a small molecule tumbling in the fast motion regime, complete saturation of one results in a 50% enhancement of the intensity of the other, provided the two relax each other solely by magnetic dipolar interactions. However, in molecules with other competing relaxation mechanisms, the magnitudes of the NOEs may often provide information on relative internuclear distances. Organic chemists found that the data from the NOE supplied critical information. For example, as Koji Nakanishi points out (*Nakanishi, Koji: First Encounter with NOE in Natural Products--the Ginkgolides*), investigators in his laboratory independently observed a NOE soon after the Anet–Bourn paper was published. Their use of the method in elucidating the structure of the ginkgolides was effective in bringing the potential importance of the NOE to the attention of other natural product chemists.^{253,254}

NOE experiments rapidly became a routine technique, so widely used that a book on the subject was soon written by Noggle and Schirmer²⁵⁵ largely to clarify the complexities involved in multispin systems with various irradiation patterns. The proton *intermolecular* Overhauser effect in a mixture of chloroform, cyclohexane, and tetramethylsilane was first reported by Kaiser,²⁵⁶ also in 1965.

For nuclei with smaller magnetic moments, such as ¹³C, the NOE was found to be of great value in intensifying signals according to the ratio of the moments of the perturbed and observed nuclei. For ¹³C, the additional factor of three in intensity (provided only dipolar relaxation is operative) became a critical factor in the early observations of this nucleus. For nuclei with negative magnetogyric ratios, such as ¹⁵N and ²⁹Si, the NOE leads to an enhanced but negative signal for dipolar interactions, but was found sometimes to result in almost complete cancellation of the signal when several relaxation mechanisms are operative.

As larger molecules began to be studied more frequently, the theory of the NOE for slowly tumbling molecules had to be taken into account. In 1972, the observation by Balaram,

Bothner-By, and Dadok²⁵⁷ of a negative intermolecular NOE in a peptide binding to a protein focused attention on another aspect of Solomon's theory of the NOE.¹⁵⁰ In the slow-motion limit, the proton–proton NOE is –1.0 rather than +0.5. This study was the forerunner of an immense amount of work in applying the NOE to biopolymers, both to obtain interproton distance information for the determination of conformation and to examine the dynamics of motion of the polymer. However, further experimental advances in pulse methods and a better understanding of spin diffusion and the transient NOE would be required before quantitative results could be obtained and interpreted. We shall return to this subject in Section 14.

Carbon-13 NMR Develops

Following the initial observations of ¹³C NMR by Lauterbur and Holm, several laboratories ventured into this difficult field, as discussed in Section 3.8. The early studies used adiabatic rapid passage, but by 1962 the first slow sweep, high-resolution spectra had been obtained.

A breakthrough in studying ¹³C NMR (which applied in many respects to other nuclei of low sensitivity such as ¹⁵N) was the adroit use of proton spin decoupling. At the Third Conference on Experimental Aspects of NMR Spectroscopy held in Pittsburgh in 1962, Lauterbur, Grant, and Shoolery independently announced enhancements of signal-to-noise (S/N) ratios in ¹³C NMR spectra obtained by double irradiation. Lauterbur and Yajko observed an enhancement of S/N in a proton-decoupling experiment, which exceeded that normally expected from the simple collapse of the proton-coupled multiplets, an early indication of the nuclear Overhauser effect in ¹³C NMR.

As Dave Grant says (*Grant, David M.: Carbon-13 Magnetic Resonance--An Exquisite NMR Garden of Surprises*), 'the proton decoupler became the crucial component in our first ¹³C observations'. With the improved sensitivity afforded by the collapse of spin multiplets, together with nuclear Overhauser enhancements, Grant and his co-workers made systematic studies of the relation of ¹³C parameters to molecular structure. Among the vast amount of information that came from this work was a striking dependence of ¹³C chemical shifts on molecular conformation.^{258,259} By capitalizing on the NOE and the multiplet collapse, it became possible to extend the scope of ¹³C studies to more dilute solutions. Furthermore, the use of double resonance provided the additional benefit of obtaining more accurate ¹³C chemical shift data by carefully measuring simultaneously two irradiating frequencies at the instant when the proton-decoupled ¹³C resonance signal is maximized. Paul and Grant²⁶⁰ analyzed the effect of the various experimental quantities upon the spectral features and suggested optimum conditions for observing proton-decoupled ¹³C spectra.

Meanwhile, Jack Roberts, who had been one of the earliest organic chemists to make extensive use of NMR, recognized the potential of ¹³C NMR now that decoupling methods could be applied. What was missing, however, was a stable, locked, frequency-sweep spectrometer that would permit the use of time averaging to enhance signal-to-noise ratios. As he describes in his historical sketch (*Roberts, John D.: A Personal NMR Odyssey*), Roberts commissioned an instrument from Varian, and in 1966 a 15 MHz digital

frequency-sweep spectrometer, based on an early Hewlett Packard frequency synthesizer, was delivered. With this instrument he and his students were able to observe ^{13}C at natural abundance on a rather routine (but still time consuming) basis, and they were even able to make the first measurements of ^{13}C – ^{13}C coupling constants at natural abundance.²⁶¹ Two additional effects still contributed to the loss of sensitivity and resolution in the ^{13}C spectra: residual splittings due to coupling with irradiated nuclei even when high decoupling power was employed, and the existence of long-range couplings in systems in which all protons are not simultaneously irradiated. When Ernst's noise modulation technique made possible true broadband decoupling, Roberts and his group made spectacular progress in obtaining and interpreting the ^{13}C spectra of a large number of molecules, including steroids,²⁶² sugars,²⁶³ and antibiotics.²⁶⁴

Grant, too, obtained a specially designed frequency-sweep ^{13}C spectrometer, and he and his colleagues broadened their ^{13}C work using decoupling to investigate the quantitative behavior of the NOE²⁶⁵ and its relation to dipolar relaxation.²⁶⁶ This work provided the underpinning for interpretation of ^{13}C signal intensities in terms of the number of carbon atoms and furnished additional bases for making spectral assignments. The problem of using proton-decoupled ^{13}C spectra for routine quantitative purposes was tackled by LaMar, who suggested the addition of suitable paramagnetic species to reduce relaxation times and eliminate the NOE, thus enabling quantitative measurements to be made, but with loss of sensitivity.

As locked, frequency-sweep spectrometers (such as the Varian HA-100) became more widely available, the use of ^{13}C NMR spread to a number of laboratories. In Estonia, Endel Lippmaa pursued ^{13}C and double resonance NMR studies, with impressive results obtained under difficult conditions since he and his group had to develop virtually all of their own instruments.

For the assignment of ^{13}C lines, the whole range of double resonance techniques that we have described in previous sections could be brought to bear. Selective, partial, and off-resonance decoupling, as well as spin-tickling and INDOR, were found to be valuable and were employed extensively.

Superconducting Magnets

As we saw in Sections 2 and 3, the quest for ever-higher magnetic field has characterized much of the development of high-resolution NMR from the earliest days. During the 1950s and early 1960s the maximum frequency for ^1H NMR had risen from 30 MHz to 40 to 60 and finally to 100 MHz. Every increase in magnetic field was followed by major advances in the quality of data available and in the range of application of NMR in chemistry. Clearly, still higher fields held great promise, but these developments had reached the upper limit of the magnetic field that could be achieved with an electromagnet due to the magnetic saturation of iron at 2.35 T (100 MHz for ^1H). Permanent magnets reach saturation at an even lower field, limiting such spectrometers to a 90 MHz proton frequency. The only place to turn was to superconducting magnets.

The superconducting properties of several niobium-based alloys at low temperature were well known, and superconducting magnets had been wound from such wire which was available commercially. The production of a magnet with the stability and homogeneity requirements needed for high-resolution NMR, however, would be no mean task. Varian assigned this job to Harry Weaver, who had designed the first 12-inch high homogeneity electromagnet at Stanford and later brought the design to Varian. Weaver's article (*Weaver, Harry E.: Historical Comments on the Early Years of Superconducting NMR*) provides a vivid description of the inception, progress, and ultimate success of a small program to develop such a superconducting magnet. He and his colleagues had to learn how to obtain and handle the then exotic liquid helium, how to design a Dewar to hold the helium and transfer the liquid, and finally how to design a high homogeneity solenoid that would remain persistently superconductive. Weaver and his team had to work out novel construction methods to ensure good thermal conductivity throughout the solenoid, and they developed homogeneity correction coils (superconducting shim coils) for the ends of the solenoid to cancel first-order field gradients. Finally they had a homogeneous, persistent magnet wound with Nb/Zr wire. As Weaver put it,

Thus, to our great pleasure and excitement, once the solenoid and its shim coils were placed in the persistent mode and the system of coils removed from the external power supplies, the field and its distribution over the sample appeared to be preserved indefinitely.

The first prototype spectrometer using this magnet operated at 200 MHz and was displayed at the Pittsburgh Conference in 1964 before it was sent to DuPont for further testing. [Varian had ensured financial support for the project by obtaining an order for a superconducting spectrometer (targeted at 300 MHz) from DuPont.] A description of the new superconducting magnet and its potential was published in *Science* in October 1964.²⁶⁷

The field was eventually raised to permit operation at 220 MHz, but a higher field was considered too risky for a commercial instrument with the then current technology. The HR-220 spectrometer provided a dramatic improvement for an NMR world that was still largely dependent on 60 MHz instruments, as illustrated in Figure 44 from a review by Ferguson and Phillips.²⁶⁸ The HR-220 became a standard product and played a particularly important role in NMR studies of biopolymers, as we shall see in Section 10. By 1970, Varian redesigned the magnet to permit operation at 300 MHz, but by that time other technology had appeared and competitive instruments began to hold sway (see Section 6.6).

The efficiency of the Dewar system is an important factor in making a supercon magnet economical. By current standards the Dewar in the HR-220 was awful, since it required refills of liquid helium twice a week when it worked at top efficiency, and more often if anything went wrong. (Currently, spectrometers with superconducting magnets having hold times up to one year are available.) While the operators complained justifiably about refills and other shortcomings of the magnet (see historical sketches by *Ferguson, Raymond C.: William D. Phillips and Nuclear Magnetic Resonance Spectroscopy at DuPont*, and *Williams, R. J. P.: The Use of NMR in Biology: Personal Reflections*), this magnet had made a quantum leap in magnetic field. Permanent magnets and electromagnets would still have wide use but all future developments centered around supercons.

Late in the 1960s the limitations of the HR-220 were becoming apparent. For example, high-order field gradients gave a water line with a very broad baseline 'hump' that severely limited many biochemical investigations, the instrument was designed for protons only, and the double resonance capability was very limited. A field/frequency lock had been deemed unnecessary for a stable supercon magnet, but with increasing need for precise measurement and control of homogeneity, this initially desirable simplification in the electronics became a shortcoming. At Oxford University, Rex Richards worked with the nearby Oxford Instruments Company to design and build a superior magnet (see *Richards, Rex: Development of NMR in Oxford*). A small prototype functioned well at 5 T and was used for various chemical studies, and in 1969 the final magnet was completed and remained persistent at 7.5 T (320 MHz for ^1H). This magnet took advantage of the newer superconductor Nb/Ti, which was much more stable than Nb/Zr. As discussed in the following section, this magnet served as the basis for the first Bruker superconducting system at 270 MHz.

Further development of Nb/Ti technology permitted the construction of spectrometers operating first at 360 MHz and then 400 MHz. Subsequent increases in persistent field strength came only in the late 1970s with the advent of the intermetallic compound Nb_3Sn as the superconductor, which was used in 470 MHz and 500 MHz instruments and eventually in 600 MHz and 750 MHz instruments (the latter at 17.3 T). Substantial technology had to be developed to fabricate a solenoid from the brittle Nb_3Sn and to make joints that remained persistent at these high field strengths.

Figure 45 summarizes the development of commercially available high-resolution NMR spectrometers as a semi-log plot of the operating frequency against the year of introduction.²⁶⁹ The figure indicates that field intensities increased roughly exponentially with time but only half as fast for superconducting magnets as for iron magnets. The break in the plot between iron and superconducting magnets is clear. Beyond 500 MHz instruments, there is a noticeable change in

Figure 45 ^1H NMR frequency of commercial NMR spectrometers as a function of year of introduction.²⁶⁹ (Reproduced by permission of Springer Verlag)

the slope as a result of the expense and practical technological problems in developing higher field magnets with immense amounts of stored energy.

Although greatest attention has been given to the development of commercial magnets and spectrometers, developments in several laboratories also played an important role in the race to higher magnetic fields. In 1968, Dadok and Sprecher began work to build a spectrometer for operation at 250 MHz and to adapt a low homogeneity Westinghouse supercon magnet to high-resolution studies. Dadok's historical sketch (*Dadok, Josef: High-Field NMR Instrumentation*) reports that:

The result was a relatively small persistent magnet for a 250 MHz spectrometer and it was equipped with four superconducting shim coils. After adding 10 mm room-temperature shim coils and an internal field/frequency lock system, we actually ended with a high-resolution spectrometer with resolution better than 0.1 Hz. This was in 1969 and we proudly presented it at the 11th ENC (1970) as the highest operating frequency spectrometer in the world. Only hours later Varian announced their first results at 300 MHz.

This spectrometer, along with others built at UCLA by Frank Anet and his colleagues at 251 and 400 MHz, broadened the base of technology and helped make superconducting magnets a way of life in NMR.

In the 1970s as commercial instruments were operating as high as 360 MHz, Dadok, Bothner-By, and co-workers at Carnegie Mellon University embarked on a project in conjunction with Intermagnetics General Corporation (IGC) to leap to 14.1 T (600 MHz). IGC was able to produce such a field from Nb_3Sn tape wound in a number of pancake coils, each superconducting itself but connected with nonsuperconducting joints. By December 1977 the first ^1H NMR spectra had been obtained. The magnet required one liter per hour of liquid helium and the spectrometer had a number of limitations, but it worked well and for almost a decade provided the only high-resolution 600 MHz system.

New Instrument Suppliers

The early history of NMR might have been very different had Varian Associates not been so quick to market commercial instruments suitable for high-resolution studies. The Bloch–Hansen patent that was assigned to Varian in 1946,

as well as a string of later patents including that for sample spinning, proved to be a strong tool in encouraging continuing investment in the improvement of the technology by Varian and in discouraging the entry of other companies into the American market. However, the patent application had been limited to the United States and companies in other countries were free to develop NMR instruments and market them outside the US.

Development of NMR began rather early in Japan where Japan Electron Optics Ltd. (JEOL), which had been formed in 1947 to develop electron microscopes, embarked on NMR instruments in 1955, and by 1956 had offered a 32 MHz instrument with an electromagnet. Subsequently this evolved into the C-60 and by 1966 the C-60-HL, which was marketed worldwide, and in 1970 to the MH-100 (miNiMaR), an early 'table-top' 100 MHz spectrometer. These instruments offered some of the first competition to the Varian A-60 and later the T-60 as 'routine' NMR instruments.

Meanwhile, in England, Associated Electrical Industries (AEI) offered an instrument based on a large electromagnet capable of a field as high as 1.8 T, with a large number of possible rf units. This AEI instrument had a rather short life span. Perkin-Elmer Ltd., however, took a different approach by developing an instrument based on a permanent magnet, the stability of which was good enough to permit the use of preprinted charts even before field/frequency lock had been introduced. Initially introduced in 1961 with lower field, the R-10 was soon upgraded to 1.4 T. Rf units for ^1H , ^{19}F , ^{31}P , and ^{11}B were available for the nuclei that were most frequently studied in the early days of NMR. With the introduction of the R-12 with solid-state electronics in 1967, Perkin-Elmer instruments were sold worldwide and competed well in the 'routine' NMR market.

In Switzerland, Hans Primas and Hans Günthard pioneered the construction of a 25 MHz, permanent magnet instrument, which in 1956 was commercialized by the Swiss company Trüb Täuber as the KIS-1. Subsequently, following Primas's development of a 75 MHz instrument, based on an electromagnet with pole caps shaped to improve homogeneity, Trüb Täuber developed the KIS-2 spectrometer equipped with a 5-ton electromagnet with a field of 2.1 T (90 MHz for ^1H NMR). Trüb Täuber was dissolved in 1965, but its spectroscopy division served as the heart of Spectrospin AG which became part of Bruker Instruments.

By 1967 Bruker had introduced the first real multinuclear NMR instrument, the HX-90. This spectrometer was marketed in the US in 1968 and with the improved technology that it offered began to challenge the Varian pre-eminence in research-grade NMR instruments. In conjunction with Oxford Instruments, Bruker was able to produce the first 270 MHz instrument by simply tripling all the frequencies from their well-developed and successful 90 MHz instrument, and later the frequencies were quadrupled to produce a 360 MHz instrument when magnet technology permitted.

Joe Dadok's historical sketch (*Dadok, Josef: High-Field NMR Instrumentation*) describes his initial forays into NMR in Brno, Czechoslovakia, where he and his colleagues developed a 30 MHz spectrometer in 1960 and later other instruments operating up to 80 MHz. These designs were commercialized by a company called TESLA BRNO, which for many years was the only supplier of NMR instruments in Eastern Europe.

Later, several other companies were to develop with specific NMR markets in mind. In 1972, Transform Technology was formed to develop and market accessories for Varian spectrometers, but this soon broadened into a full-scale NMR instrument company under the management first of Nicolet Instruments and then of General Electric. IBM entered the NMR field in 1980 and for several years marketed instruments produced by Bruker to IBM specifications. Gary Maciel's historical sketch (*Maciel, Gary E.: A Little Polarization Can be Good for You*) describes the origin of Chemagnetics in 1978, initially to develop probes for NMR studies in solids. This company, too, broadened its scope to produce complete spectrometers for the study of both solids and liquids.

Table 1 provides a summary of the high-resolution spectrometers marketed by the principal NMR instrument companies up to 1994.

For NMR spectroscopists, the sudden onset of competition meant a greater choice of instruments at reasonable cost. For the development of NMR technology, the broadening of the field to an international scope meant that new methods could be invented and commercialized at an ever-faster rate. This existence of a number of NMR instrument companies would have important consequences in the speed of development of the next major advance in NMR—Fourier transform methods.

FOURIER TRANSFORM NMR

The development and widespread use of Fourier transform methods represents a real watershed in the history of NMR. As we have seen, NMR advances were largely driven by applications to chemistry with its requirements for high resolution and high magnetic field. Sensitivity remained low, and nuclei with small magnetic moments or low isotopic abundance (such as ^{13}C) could be investigated only with great difficulty. High-resolution spectra were obtained by slow scan, so that the time-averaging computers were largely limited in applicability to the relatively small number of repetitions that could be obtained in an overnight run. Meanwhile, most of the NMR technology using powerful rf pulses remained largely in the physicist's armamentarium and appeared to be inapplicable to the multiline spectra characteristic of virtually all interesting chemical systems.
